Abstract

A general linear response method for deriving improved estimates of correlations in the variational Bayes framework is presented. Three applications are given and it is discussed how to use linear response as a general principle for improving mean field approximations.

1 Introduction

Variational and related mean field techniques have attracted much interest as methods for performing approximate Bayesian inference, see e.g. [1]. The maturity of the field has recently been underpinned by the appearance of the variational Bayes method [2, 3, 4] and associated software making it possible with a window based interface to define and make inference for a diverse range of graphical models [5, 6].

Variational mean field methods have shortcomings as thoroughly discussed by Mackay [7]. The most important is that it based upon the variational assumption of independent variables. In many cases where the effective coupling between the variables are weak this assumption works very well. However, if this is not the case, the variational method can grossly underestimate the width of marginal distributions because variance contributions induced by other variables are ignored as a consequence of the assumed independence. Secondly, the variational approximation may be non-convex which is indicated by the occurrence of multiple solutions for the variational distribution. This is a consequence of the fact that a possibly complicated multi-modal distribution is approximated by a simpler uni-modal distribution.

Linear response (LR) is a perturbation technique that gives an improved estimate of the correlations between the stochastic variables by expanding around the solution to variational distribution [8]. This means that we can get non-trivial estimates of correlations from the factorizing variational distribution. In many machine learning models, e.g. Boltzmann machine learning [9] or probabilistic Independent Component Analysis [3, 10], the M-step of the EM algorithm depend upon the covariances of the variables and LR has been applied with success in these cases [9, 10].

Variational calculus is in this paper used to derive a general linear response correction from the variational distribution. It is demonstrated that the variational LR correction can be calculated as systematically the variational distribution in the Variational Bayes framework

(albeit at a somewhat higher computational cost). Three applications are given: a model with a quadratic interactions, a Bayesian model for estimation of mean and variance of a 1D Gaussian and a Variational Bayes mixture of multinomials (i.e. for modeling of histogram data). For the two analytically tractable models (the Gaussian and example two above), it is shown that LR gives the correct analytical result where the variational method does not. The need for structured approximations, see e.g. [5] and references therein, that is performing exact inference for solvable subgraphs, might thus be eliminated by the use of linear response.

We define a general probabilistic model \mathcal{M} for data \mathbf{y} and model parameters \mathbf{s} : $p(\mathbf{s}, \mathbf{y}) = p(\mathbf{s}, \mathbf{y}|\mathcal{M})$. The objective of a Bayesian analysis are typically the following: to derive the marginal likelihood $p(\mathbf{y}|\mathcal{M}) = \int d\mathbf{s} p(\mathbf{s}, \mathbf{y}|\mathcal{M})$ and marginal distributions e.g. the one-variable $p_i(s_i|\mathbf{y}) = \frac{1}{p(\mathbf{y})} \int \prod_{k \neq i} ds_k p(\mathbf{s}, \mathbf{y})$ and the two-variable $p_{ij}(s_i, s_j|\mathbf{y}) = \frac{1}{p(\mathbf{y})} \int \prod_{k \neq i, j} ds_k p(\mathbf{s}, \mathbf{y})$. In this paper, we will only discuss how to derive linear response approximations to marginal distributions. Linear response corrected marginal likelihoods can also be calculated, see Ref. [11].

The paper is organized as follows: in section 2 we discuss how to use the marginal likelihood as a generating functions for deriving marginal distributions. In section 4 we use this result to derive the linear response approximation to the two-variable marginals and derive an explicit solution of these equations in section 5. In section 6 we discuss why LR in the cases where the variational method gives a reasonable solution will give an even better result. In section 7, we give the three applications and in section we conclude and discuss how to combine the mean field approximation (variational, Bethe, ...) with linear response to give more precise mean field approaches.

After finishing this paper the authors have become aware of the work of Welling and Teh [12, 13] which also contains the result eq. (8) and furthermore extend linear response to the Bethe approximation, give several general results for the properties of linear response estimates and derive belief propagation algorithms for computing the linear response estimates. The new contributions of this paper compared to Refs. [12, 13] are the explicit solution of the linear response equations, the discussion of the expected increased quality of linear response estimates, the applications of linear response to concrete examples especially in relation to variational Bayes and the discussion of linear response and mean field methods beyond variational.

2 Generating Marginal Distributions

In this section it is shown how exact marginal distributions can be obtained from functional derivatives of a generating function (the log partition function). In the derivation of the variational linear response approximation to the two-variable marginal distribution $p_{ij}(s_i, s_j|\mathbf{y})$, we can use result by replacing the exact marginal distribution with the variational approximation. To get marginal distributions we introduce a generating function

$$Z[\mathbf{a}] = \int d\mathbf{s} p(\mathbf{s}, \mathbf{y}) e^{\sum_i a_i(s_i)} \quad (1)$$

which is a functional of the arbitrary functions $a_i(s_i)$ and \mathbf{a} is shorthand for the vector of functions $\mathbf{a} = (a_1(s_1), a_2(s_2), \dots, a_N(s_N))$. We can now obtain the marginal distribution $p(s_i|\mathbf{y}, \mathbf{a})$ by taking the functional derivative¹ with respect to $a_i(s_i)$:

$$\frac{\delta}{\delta a_i(s_i)} \ln Z[\mathbf{a}] = \frac{e^{a_i(s_i)}}{Z[\mathbf{a}]} \int \prod_{k \neq i} \left\{ d\hat{s}_k e^{a_k(\hat{s}_k)} \right\} p(\hat{\mathbf{s}}, \mathbf{y}) = p_i(s_i|\mathbf{y}, \mathbf{a}) . \quad (2)$$

¹The functional derivative is defined by $\frac{\delta a_j(s_j)}{\delta a_i(s_i)} = \delta_{ij} \delta(s_i - s_j)$ and the chain rule.

Setting $\mathbf{a} = 0$ above gives the promised result. The next step is to take the second derivative. This will give us a function that are closely related to the two-variable marginal distribution. A careful derivation gives

$$\begin{aligned} B_{ij}(s_i, s'_j) &\equiv \left. \frac{\delta^2 \ln Z[\mathbf{a}]}{\delta a_j(s'_j) \delta a_i(s_i)} \right|_{\mathbf{a}=0} = \left. \frac{\delta p_i(s_i|\mathbf{y}, \mathbf{a})}{\delta a_j(s'_j)} \right|_{\mathbf{a}=0} \\ &= \delta_{ij} \delta(s_i - s'_j) p_i(s_i|\mathbf{y}) + (1 - \delta_{ij}) p_{ij}(s_i, s'_j|\mathbf{y}) - p_i(s_i|\mathbf{y}) p_j(s'_j|\mathbf{y}) \end{aligned} \quad (3)$$

Performing an average of $s_i^m (s'_j)^n$ over $B_{ij}(s_i, s'_j)$, it is easy to see that $B_{ij}(s_i, s'_j)$ gives the 'mean-subtracted' marginal distributions. In the two next sections, variational approximations to the single variable and two-variable marginals are derived.

3 Variational Learning

In many models of interest, e.g. mixture models, exact inference scales exponentially with the size of the system. It is therefore of interest to come up with polynomial approximations. A prominent method is the variational, where a simpler factorized distribution $q(\mathbf{s}) = \prod_i q_i(s_i)$ is used instead of the posterior distribution. Approximations to the marginal distributions $p_i(s_i|\mathbf{y})$ and $p_{ij}(s_i, s_j|\mathbf{y})$ are now simply $q_i(s_i)$ and $q_i(s_i)q_j(s_j)$. The purpose of this paper is to show that it is possible within the variational framework to go beyond the factorized distribution for two-variable marginals. For that purpose we need the $q(\mathbf{s})$ which found the distribution which minimizes the KL-divergence or 'distance' between $q(\mathbf{s})$ and $p(\mathbf{s}|\mathbf{y})$:

$$KL(q(\mathbf{s})||p(\mathbf{s}|\mathbf{y})) = \int d\mathbf{s} q(\mathbf{s}) \ln \frac{q(\mathbf{s})}{p(\mathbf{s}|\mathbf{y})}. \quad (4)$$

The variational approximation to the Likelihood is obtained from

$$-\ln Z_v[\mathbf{a}] = \int d\mathbf{s} q(\mathbf{s}) \ln \frac{q(\mathbf{s})}{p(\mathbf{s}, \mathbf{y}) e^{\sum_k a_k(\hat{s}_k)}} = -\ln Z[\mathbf{a}] + KL(q(\mathbf{s})||p(\mathbf{s}|\mathbf{y}, \mathbf{a})),$$

where \mathbf{a} has been introduced to be able use $q_i(s_i|\mathbf{a})$ as a generating function. Introducing Lagrange multipliers $\{\lambda_i\}$ as enforce normalization and maximizing $KL + \sum_i \lambda_i (\int ds_i q_i(s_i) - 1)$ with respect to $q_i(s_i)$ and λ_i , one finds

$$q_i(s_i|\mathbf{a}) = \frac{e^{a_i(s_i) + \int \prod_{k \neq i} \{ds_k q_k(s_k|\mathbf{a})\} \ln p(\mathbf{s}, \mathbf{y})}}{\int d\hat{s}_i e^{a_i(\hat{s}_i) + \int \prod_{k \neq i} \{d\hat{s}_k q_k(\hat{s}_k|\mathbf{a})\} \ln p(\hat{\mathbf{s}}, \mathbf{y})}. \quad (5)$$

Note that $q_i(s_i|\mathbf{a})$ depends upon all \mathbf{a} through the implicit dependence in the q_k s appearing on the right hand side. Writing the posterior in terms of 'interaction potentials'

$$p(\mathbf{s}, \mathbf{y}) = \prod_i \psi_i(s_i) \prod_{i>j} \psi_{i,j}(s_i, s_j) \dots, \quad (6)$$

it is easy to see that potentials that do not depend upon s_i will drop out of variational distribution. A similar property will be used below to simplify the variational two-variable marginals.

4 Variational Linear Response

Eq. (3) shows that we can obtain the two-variable marginal as the derivative of the marginal distribution. To get the variational linear response approximation we exchange the exact marginal with the variational approximation eq. (5) in eq. (3). In section 6 a short proof is

given for why one can expect the variational approach to work in many cases and why the linear response approximation gives improved estimates of correlations in these cases.

Defining the variational 'mean subtracted' two-variable marginal as

$$C_{ij}(s_i, s'_j | \mathbf{a}) \equiv \frac{\delta q_i(s_i | \mathbf{a})}{\delta a_j(s'_j)}, \quad (7)$$

it is now possible to derive an expression corresponding to eq. (3). What makes the derivation a bit cumbersome is that it necessary to take into account the implicit dependence of $a_j(s'_j)$ in $q_k(s_k | \mathbf{a})$ and the result will consequently be expressed as a set of linear integral equations in $C_{ij}(s_i, s'_j | \mathbf{a})$. These equations can be solved explicitly, see section 5 or can as suggested by Welling and Teh [12, 13] be solved by belief propagation.

Taking into account both explicit and implicit a dependence we get the variational linear response theorem:

$$\begin{aligned} C_{ij}(s_i, s'_j | \mathbf{a}) = & \delta_{ij} \{ \delta(s_i - s'_j) q_i(s_i | \mathbf{a}) - q_i(s_i | \mathbf{a}) q_j(s'_j | \mathbf{a}) \} \\ & + q_i(s_i | \mathbf{a}) \sum_{l \neq i} \int \prod_{k \neq i} ds_k \prod_{k \neq i, l} q_k(s_k | \mathbf{a}) C_{lj}(s_l, s'_j | \mathbf{a}) \\ & \times \left\{ \ln p(\mathbf{s}, \mathbf{y}) - \int ds_i q_i(s_i | \mathbf{a}) \ln p(\mathbf{s}, \mathbf{y}) \right\}. \end{aligned} \quad (8)$$

The first term represents the normal variational correlation estimate and the second term is linear response correction which expresses the coupling between the two-variable marginals.

Using the factorization of the posterior eq. (6), it is easily seen that potentials that do not depend on both s_i and s_l will drop out in the last term. This property will make the calculations for the most variational Bayes models quite simple since this means that one only has to sum over variables that are directly connected in the graphical model.

5 Explicit Solution

The integral equation can be simplified by introducing the symmetric kernel

$$K_{ij}(s, s') = (1 - \delta_{ij}) (\langle \ln p(\mathbf{s}, \mathbf{y}) \rangle_{q \setminus (i,j)} - \langle \ln p(\mathbf{s}, \mathbf{y}) \rangle_{q \setminus j} - \langle \ln p(\mathbf{s}, \mathbf{y}) \rangle_{q \setminus i} + 1), \quad (9)$$

where the brackets $\langle \dots \rangle_{q \setminus (i,j)}$ denote expectations over all variables, except for s_i and s_j and similarly for $\langle \dots \rangle_{q \setminus i}$. One can easily show that $\int ds q_i(s) K_{ij}(s, s') = 0$. Writing C in the form

$$C_{ij}(s, s') = q_i(s) q_j(s') \left\{ \delta_{ij} \left(\frac{\delta(s - s')}{q_j(s')} - 1 \right) + R_{ij}(s, s') \right\}, \quad (10)$$

we obtain an integral equation for the function R

$$R_{ij}(s, s') = \sum_l \int d\tilde{s} q_l(\tilde{s}) K_{il}(s, \tilde{s}) R_{lj}(\tilde{s}, s') + K_{ij}(s, s'). \quad (11)$$

For many applications, kernels can be written in the form of sums of pairwise multiplicative 'interactions' i.e.

$$K_{ij}(s, s') = \sum_{\alpha \alpha'} J_{ij}^{\alpha \alpha'} \phi_i^\alpha(s) \phi_j^{\alpha'}(s') \quad (12)$$

with $\langle \phi_i^\alpha \rangle_q = 0$ for all i and α then the solution will be on the form $R_{ij}(s, s') = \sum_{\alpha \alpha'} A_{ij}^{\alpha \alpha'} \phi_i^\alpha(s) \phi_j^{\alpha'}(s')$. The integral equation reduces to a system of linear equations for the coefficients $A_{ij}^{\alpha \alpha'}$.

We now discuss the simplest case where $K_{ij}(s, s') = J_{ij}\phi_i(s)\phi_j(s')$. This is obtained if the model has only pairwise interactions of the quadratic form $\psi_{ij}(s, s') = e^{J_{ij}\Phi_i(s)\Phi_j(s')}$, where $\phi_i(s) = \Phi_i(s) - \langle \Phi_i \rangle_q$. Using $R_{ij}(s, s') = A_{ij}\phi_i(s)\phi_j(s')$ and augmenting the matrix of J_{ij} 's with the diagonal elements $J_{ii} \equiv -\frac{1}{\langle \phi_i^2 \rangle_q}$ yield the solution

$$A_{ij} = -J_{ii}J_{jj} \left(D(J_{ii}) - \mathbf{J}^{-1} \right)_{ij}, \quad (13)$$

where $D(J_{ii})$ is a diagonal matrix with entries J_{ii} . Using (10), this result immediately leads to the expression for the correlations

$$\langle \phi_i \phi_j \rangle = \langle \Phi_i \Phi_j \rangle - \langle \Phi_i \rangle \langle \Phi_j \rangle = -(\mathbf{J}^{-1})_{ij}. \quad (14)$$

6 Why Linear Response Works

It may seem paradoxical that an approximation which is based on uncorrelated variables allows us to obtain a nontrivial result for the neglected correlations. To shed more light on this phenomenon, we would like to see how the true partition function, which serves as a generating function for expectations, differs from the mean field one when the approximating mean field distribution q are close. We will introduce into the generating function eq. (1) the parameter ϵ :

$$Z_\epsilon[\mathbf{a}] = \int ds q(\mathbf{s}) e^{\epsilon(\sum_i a_i(s_i) + \ln p(\mathbf{s}|\mathbf{y}) - \ln q(\mathbf{a}))} \quad (15)$$

which serves as a bookkeeping device for collecting relevant terms, when $\ln p(\mathbf{s}|\mathbf{y}) - \ln q(\mathbf{s})$ is assumed to be small. At the end we will set $\epsilon = 1$ since $Z[\mathbf{a}] = Z_{\epsilon=1}[\mathbf{a}]$. Then expanding the partition function to first order in ϵ , we get

$$\begin{aligned} \ln Z_\epsilon[\mathbf{a}] &= \epsilon \left(\sum_i \langle a_i(s_i) \rangle_q + \langle \ln p(\mathbf{s}|\mathbf{y}) - \ln q(\mathbf{s}) \rangle_q \right) + O(\epsilon^2) \\ &= \epsilon \left(\sum_i \langle a_i(s_i) \rangle_q - KL(q||p) \right) + O(\epsilon^2). \end{aligned} \quad (16)$$

Keeping only the linear term, setting $\epsilon = 1$ and inserting the minimizing mean field distribution for q yields

$$p_i(s|\mathbf{y}, \mathbf{a}) = \frac{\delta \ln Z}{\delta a_i(s)} = q_i(s|\mathbf{a}) + O(\epsilon^2). \quad (17)$$

Hence the computation of the correlations via

$$B_{ij}(s, s') = \frac{\delta^2 \ln Z}{\delta a_i(s) \delta a_j(s')} = \frac{\delta p_i(s|\mathbf{a})}{\delta a_j(s')} = \frac{\delta q_i(s|\mathbf{a})}{\delta a_j(s')} + O(\epsilon^2) = C_{ij}(s, s') + O(\epsilon^2) \quad (18)$$

can be assumed to incorporate correctly effects of *linear order* in $\ln p(\mathbf{s}|\mathbf{a}) - \ln q(\mathbf{s})$. On the other hand, one should expect that $p(s_i, s_j|\mathbf{y}) - q_i(s_i)q_j(s_j)$ to be order ϵ . Although the above does not prove that diagonal correlations are estimated better from $C_{ii}(s, s')$ than by using $q_i(s)$, ones often observes that in practice, see below.

7 Applications

7.1 Quadratic Interactions

The quadratic interaction model— $\ln \psi_{ij}(s_i, s_j) = s_i J_{ij} s_j$ and arbitrary $\psi(s_i)$, i.e. $\ln p(\mathbf{s}, \mathbf{y}) = \sum_i \ln \psi_i(s_i) + \frac{1}{2} \sum_{i \neq j} s_i J_{ij} s_j + \text{constant}$ —is used in many contexts, e.g.

the Boltzmann machine, independent component analysis and the Gaussian process prior. For this model we can immediately apply the result eq. (14) to get

$$\langle s_i s_j \rangle - \langle s_i \rangle \langle s_j \rangle = -(\mathbf{J}^{-1})_{ij} \quad (19)$$

where we have set $J_{ii} = -1/(\langle s_i^2 \rangle_q - \langle s_i \rangle_q^2)$.

We can apply this to the Gaussian model $\ln \psi_i(s_i) = h_i s_i + A_i s_i^2/2$. The variational distribution is Gaussian with variance $-1/A_i$ (and covariance zero). Hence, we can set $J_{ii} = A_i$. The mean is $-\mathbf{J}^{-1}\mathbf{h}$. The exact marginals have mean $-\mathbf{J}^{-1}\mathbf{h}$ and covariance $-\mathbf{J}^{-1}$. The difference can be quite dramatic, e.g. in two dimensions for $\mathbf{J} = \begin{pmatrix} 1 & \epsilon \\ \epsilon & 1 \end{pmatrix}$, we get $\mathbf{J}^{-1} = \frac{1}{1-\epsilon^2} \begin{pmatrix} 1 & -\epsilon \\ -\epsilon & 1 \end{pmatrix}$. The variance estimates are $1/J_{ii} = 1$ for variational and $[\mathbf{J}^{-1}]_{ii} = 1/(1-\epsilon^2)$ for the exact case. The latter diverges for completely correlated variable, $\epsilon \rightarrow 1$ illustrating that the variational covariance estimate breaks down when the interaction between the variables are strong.

A very important remark should be made at this point: although the covariance eq. (19) comes out correctly, the LR method *does not reproduce the exact two variable marginals*, i.e. the distribution eq. (10) plus the sum of the product of the one variable marginals is not a Gaussian distribution.

7.2 Mean and Variance of 1D Gaussian

A one dimensional Gaussian observation model $p(y|\mu, \beta) = \sqrt{\beta/2\pi} \exp(-\beta(x-\mu)^2/2)$, $\beta = 1/\sigma^2$ with a Gaussian prior over the mean and a Gamma prior over β [7] serves as another example of where linear response as opposed to variational is exact. The N example likelihood can be rewritten as

$$p(\mathbf{y}|\mu, \beta) = \left(\frac{\beta}{2\pi}\right)^{\frac{N}{2}} \exp\left(-\frac{\beta}{2}N\hat{\sigma}^2 - \frac{\beta}{2}N(\mu - \bar{y})^2\right), \quad (20)$$

where \bar{y} and $\hat{\sigma}^2 = \sum_i (y_i - \bar{y})^2/N$ are the empirical mean and variance. We immediately recognize $-\frac{\beta}{2}N(\mu - \bar{y})^2$ as the interaction term. Choosing non-informative priors— $p(\mu)$ flat and $p(\beta) \propto 1/\beta$ —the variational distribution $q_\mu(\mu)$ becomes Gaussian with mean \bar{y} and variance $1/N\langle\beta\rangle_q$ and $q_\beta(\beta)$ becomes a Gamma distribution $\Gamma(\beta|b, c) \propto \beta^{c-1}e^{-\beta/b}$, with parameters $c_q = N/2$ and $1/b_q = \frac{N}{2}(\hat{\sigma}^2 + \langle(\mu - \bar{y})^2\rangle_q)$. The mean and variance of Gamma distribution is given by bc and b^2c . Solving with respect to $\langle(\mu - \bar{y})^2\rangle_q$ and $\langle\beta\rangle_q$ give $1/b_q = \frac{N\hat{\sigma}^2}{2} \frac{N}{N-1}$. Exact inference gives $c_{\text{exact}} = (N-1)/2$ and $1/b_{\text{exact}} = \frac{N\hat{\sigma}^2}{2}$ [7]. A comparison shows that the mean bc is the same in both cases whereas variational underestimates the variance b^2c . This is a quite generic property of the variational approach.

The LR correction to the covariance is easily derived from (14) setting $J_{12} = -N/2$ and $\phi_1(\beta) = \beta - \langle\beta\rangle_q$ and $\phi_2(\mu) = (\mu - \bar{y})^2$. This yields $J_{11} = -1/\langle\phi_1^2(\beta)\rangle = -1/b_q\langle\beta\rangle_q$. Using $\langle(\mu - \bar{y})^2\rangle_q = 1/N\langle\beta\rangle_q$ and $\langle(\mu - \bar{y})^4\rangle_q = 3\langle(\mu - \bar{y})^2\rangle_q^2$, we have $J_{22} = -1/\langle\phi_2^2(\mu)\rangle = -N^2\langle\beta\rangle_q/2$. Inverting the 2×2 matrix \mathbf{J} , we immediately get

$$\langle\phi_1^2\rangle = \text{Var}(\beta) = -(\mathbf{J}^{-1})_{11} = b_q\langle\beta\rangle_q/(1 - b_q/2\langle\beta\rangle_q)$$

Inserting the result for $\langle\beta\rangle_q$, we find that this is in fact the correct result.

7.3 Variational Bayes Mixture of Multinomials

As a final example, we take a mixture model of practical interest and show that linear response corrections straightforwardly can be calculated. Here we consider the problem of

modeling histogram data $y_{n,j}$ consisting of N histograms each with D bins: $n = 1, \dots, N$ and $j = 1, \dots, D$. We can model this with a mixture of multinomials (Lars Kai Hansen 2003, in preparation):

$$p(\mathbf{y}_n | \boldsymbol{\pi}, \boldsymbol{\rho}) = \sum_{k=1}^K \pi_k \prod_{j=1}^D \rho_{kj}^{y_{nj}}, \quad (21)$$

where π_k is the probability of the k th mixture and ρ_{kj} is the probability of observing the j th histogram given we are in the k th component, i.e. $\sum_k \pi_k = 1$ and $\sum_j \rho_{kj} = 1$. Eventually in the variational Bayes treatment we will introduce Dirichlet priors for the variables. But the general linear response expression is independent of this. To rewrite the model such that it is suitable for a variational treatment—i.e. in a product form—we introduce hidden (Potts) variables $\mathbf{x}_n = \{x_{nk}\}$, $x_{nk} \in \{0, 1\}$ and $\sum_k x_{nk} = 1$ and write the joint probability of observed and hidden variables as:

$$p(\mathbf{y}_n, \mathbf{x}_n | \boldsymbol{\pi}, \boldsymbol{\rho}) = \prod_{k=1}^K \left(\pi_k \prod_{j=1}^D \rho_{kj}^{y_{nj}} \right)^{x_{nk}}. \quad (22)$$

Summing over all possible \mathbf{x}_n vectors, we recover the original observation model.

We can now identify the interaction terms in $\sum_n \ln p(\mathbf{y}_n, \mathbf{x}_n, \boldsymbol{\pi}, \boldsymbol{\rho})$ as $x_{nk} \ln \pi_k$ and $y_{nj} x_{nk} \ln \rho_{kj}$. Generalizing eq. (8) to sets of variables, we will compute the following correlations $C(\boldsymbol{\pi}, \boldsymbol{\pi}')$, $C(\boldsymbol{\pi}, \boldsymbol{\rho}')$ and $C(\boldsymbol{\rho}_k, \boldsymbol{\rho}'_{k'})$. It will turn out that two variable marginal distributions involving the hidden variables—the number of which scales with the number of examples—can be eliminated. This is a consequence of the fact that the hidden variables can be eliminated analytically in the original model. The computation of correlation are thus only polynomial in the number of parameters making computation of correlations attractive even for mixture models.

This model fall in the simple two-variable case and can thus be solve using the general eqs. in section 5. Here we use eq. 8 to illustrate how to eliminate the hidden variables. We start out by calculating the correlation between $\boldsymbol{\pi}$ and an arbitrary set of variables $\mathbf{z} = \{\boldsymbol{\pi}, \boldsymbol{\rho}_{k'}\}$:

$$\begin{aligned} R(\boldsymbol{\pi}, \mathbf{z}') &= q(\boldsymbol{\pi}) \sum_k (\ln \pi_k - \langle \ln \pi_k \rangle) \sum_n \int d\mathbf{x}_n C(\mathbf{x}_n, \mathbf{z}') x_{nk} \\ C(\mathbf{x}_n, \mathbf{z}') &= q(\mathbf{x}_n) \sum_{k'} (x_{nk'} - \langle x_{nk'} \rangle) \\ &\quad \times \left\{ \int d\boldsymbol{\pi}' C(\boldsymbol{\pi}', \mathbf{z}') \ln \pi_{k'} + \sum_j y_{nj} \int d\boldsymbol{\rho}_{k'} C(\boldsymbol{\rho}_{k'}, \mathbf{z}') \ln \rho_{k'j} \right\}. \end{aligned}$$

Eliminating $C(\mathbf{x}_n, \mathbf{z}')$ above gives

$$\begin{aligned} C(\boldsymbol{\pi}, \mathbf{z}') &= \delta_{\boldsymbol{\pi}, \mathbf{z}'} \{ \delta(\boldsymbol{\pi} - \mathbf{z}') q(\boldsymbol{\pi}) - q(\boldsymbol{\pi}) q(\mathbf{z}') \} + q(\boldsymbol{\pi}) \sum_{kk'} (\ln \pi_k - \langle \ln \pi_k \rangle) \\ &\quad \times \left\{ F_{kk'} \int d\boldsymbol{\pi}' C(\boldsymbol{\pi}', \mathbf{z}') \ln \pi_{k'} + \sum_j G_{kk'}^j \int d\boldsymbol{\rho}_{k'} C(\boldsymbol{\rho}_{k'}, \mathbf{z}') \ln \rho_{k'j} \right\}, \end{aligned}$$

where we have introduced $F_{kk'}^n \equiv \int d\mathbf{x}_n q(\mathbf{x}_n) x_{nk} (x_{nk'} - \langle x_{nk'} \rangle) + \langle x_{nk} \rangle \langle x_{nk'} \rangle$, $F_{kk'} \equiv \sum_n F_{kk'}^n$ and $G_{kk'}^j \equiv \sum_n y_{nj} F_{kk'}^j$. A similar equation for $C(\boldsymbol{\rho}_k, \mathbf{z}')$ can straight forwardly be calculated. Analogous to the quadratic interaction example above we have to solve $K + DK$ linear equations. This result shows that we can eliminate the hidden variables such that the equations that we eventually have to solve to get the correlations estimates will not scale with the number of observations. In a future work, the different correlation estimates will be compared in practice.

8 Conclusion and Outlook

In this paper we have shown that it is possible to extend linear response to completely general variational distributions and solve the linear response equations explicitly. We have given three applications that shows 1. that linear response provides approximations of increased quality for two-variable marginals and 2. linear response is practical for variational Bayes models. Together this suggests that building linear response into variational Bayes software such as VIBES [5, 6] would be useful.

Welling and Teh [12, 13] have, as mentioned in the introduction, shown how to apply the general linear response methods to the Bethe approximation. However, the usefulness of linear response even goes beyond this: if we can come up with a better tractable approximation to the marginal distribution $q(s_i)$ with some free parameters, we can tune these parameters by requiring consistency between $q(s_i)$ and the linear response estimate of the diagonal of the two-variable marginals eq. (8):

$$C_{ii}(s_i, s'_i) = \delta(s_i - s'_i)q(s_i) - q(s_i)q(s'_i). \quad (23)$$

This design principle can be generalized to models that give non-trivial estimates of two-variable marginals such as Bethe. It might not be possible to match the entire distribution for a tractable choice of $q(s_i)$. In that case it is possibly to only require consistency for some statistics. The adaptive TAP approach [11]—so far only studied for quadratic interactions—can be viewed in this way. Generalizing this idea to general potentials, general mean field approximations, deriving the corresponding marginal likelihoods and deriving guaranteed convergent algorithms for the approximations are under current investigation.
