Translation of a Subset of RSL into Java

Ulrik Hjarnaa, s991422

12th November 2004

Preface

This thesis is the final requirement for obtaining the degree Master of Science in Engineering. The work was carried out at the Computer Science and Engineering section at the Institute of Informatics and Mathematical Modelling at the Technical University of Denmark. The duration of the project was from the 10th of May 2004 until the 12th of November 2004.

The project was supervised by Associate Professor, Ph.D. Anne E. Haxthausen and Associate Professor Hans Bruun.

I would like to thank my supervisors for constructive critisism and inspiration during the project. I would also like to thank the following people for comments on the report as well as proof reading: Martin W. Andersen and Poul-Henrik Worm.

Special thanks to my fiancée Ulla Berg Nielsen and my daughter Emma Berg Hjarnaa for support, understanding and patience throughout the project.

Lyngby, 11th November 2004

Ulrik Hjarnaa

Abstract

There exist a number of specification languages which are used for specifying the design and behaviour of software systems. Furthermore, a number of programming languages exist, which are used for implementation of software systems. This thesis focuses on a possible translation from the specification language RSL into the programming language Java.

This work identifies a translatable subset of the applicative part of RSL and gives suggestions for a translation of a subset of this into Java. The work focuses on the parts of RSL which have a direct translation in Java.

Based on these translations a prototype of a tool for carrying out the translation has been developed.

The tool has been developed using a combination of techniques. The front end has been developed using a tool for generating a lexer and a parser. The back end has been developed using the object–oriented visitor design pattern. The main part of the tool has been developed using a bootstrapping process. The main part of the tool was specified in RSL and translated using the tool itself.

Keywords: RAISE, RSL, Java, translation, bootstrapping.

Resumé

Der findes en række specifikationssprog som anvendes til at specificere designet af og egenskaber for software systemer. Derudover findes der en række programmeringssprog, som bliver anvendt til at implementere software systemer. Dette eksamensprojekt fokuserer på en mulig oversættelse fra specifikationssproget RSL til programmeringsproget Java.

Dette projekt identificerer en oversætbar delmængde af den applikative del af RSL og giver forslag til en oversættelse af en delmængde af denne til Java. Projektet fokuserer på de dele af RSL som har en direkte oversættelse i Java.

Baseret på disse oversættelser er der udviklet en prototype af et værktøj til at udføre af oversættelsen.

Værktøjet er blevet udviklet under anvendelse af en kombination af teknikker. Forenden er blevet udviklet under anvendelse af et værktøj til at generere en lexer og en parser. Bagenden er blevet udviklet under anvendelse af det objekt orienterede visitor design pattern. Hoveddelen af værktøjet er blevet udviklet under anvendelse af en bootstrapping proces. Hoveddelen af værktøjet blev specificeret i RSL og oversat med værktøjet selv.

Nøgleord: RAISE, RSL, Java, oversættelse, bootstrapping.

Notation Guide

Overall notation will attempt to follow well established guidelines where possible. The following conventions have been used. Single keywords or very short examples of code:

RSL keywords are in ordinary type face written: **value**.

RSL specifications are in ordinary type face written: `function`.

RSL Scheme and Object names are in ordinary type face written: MY_MODULE.

Java keywords and names are in ordinary type face written: *Object*.

Java code is in ordinary type face written: equals.

ANTLR grammar is in ordinary type face written: `scheme_def`.

Definitions of translations are written as an RSL specification followed by a listing of Java source code both of which may include mathematical symbols for indexing identifiers. Examples of translations, longer specifications in RSL and listings of Java source code are written as numbered examples.

Chapter 1

Introduction

In the process of developing software, there are several methods or approaches. These methods range from rather ad hoc ones to methods which are very systematic and well organized. Each of the approaches has a number of strengths and weaknesses. In the category of systematic methods there are several kinds, some of which are visually based, and some based on mathematics. Most of the mathematically based methods for software development have an accompanying language or notation for writing specifications of software.

Steps in a mathematically based method include writing a specification in the accompanying language or notation and implementing the specification in a programming language. It is the similarities between the final specification and the implementation which are of interest in this project. When comparing implementations of different specifications there are often a number of constructs in the specification language, which are implemented in the same way in the programming language.

This leads to the idea that a specification language or at least a subset of a specification language can be translated systematically to a programming language. If it is possible to define a systematic translation, then it may be possible to develop a tool for carrying out the translation.

This project focuses on translation from the formal specification language (RSL) RAISE Specification Language into the programming language Java.

RAISE is a formal method for software development. It is an abbreviation for Rigorous Approach to Industrial Software Engineering. RAISE consists of three parts:

- A method for software development: RAISE [12].
- A specification language: RSL[11].

- A set of tools for the specifications: rsltc [10], eden [15].

RSL is a wide spectrum specification language based on mathematics. It is a high level language, and it offers many means for specifying the behaviour of software. RSL offers posibilities of writing applicative specifications, algebraic specification and imperative specifications.

Java is a general purpose imperative programming language. It is a high level language meaning that complicated operations may be expressed using simple statements and predefined objects and methods. Java is aimed at being portable between different hardware platforms: "Write once, run everywhere". The idea of being highly portable makes it well suited for an automatic translation, since the translation does not have to deal with different platforms. The source code generated should be able to run on all machines, for which Java is available.

Some specification styles in RSL are not well suited for implementation in a programming language. There are two issues which seems problematic in a translation to a programming language. In RSL, it is possible to underspecify the values in a specification, which makes it impossible to determine the exact value. Furthermore, the syntax of RSL allows for implicit definitions, which makes it very difficult to determine a value.

In general these implicit ways of specification cannot be implemented in an imperative programming language, because in an imperative programming language everything must be specified explicitly. This is the reason why only a subset of RSL can be translated into Java.

1.1 Thesis Objectives

The idea presented above that a subset of the specification language RSL can be translated systematically to the programming language Java, has lead to the following objectives:

1. Definition of a *translation* from a subset of RSL into Java.
2. Development of a tool for translating from RSL into Java, called a *translator*.

1.2 Requirements of the Developments

The two objectives listed above have lead to a number of requirements for each of them. These requirements are described and discussed in the following.

Requirements of Translation

1. The translation from RSL into Java must be semantically equivalent to the specification in RSL.

2. In the Java translated from the specification it should be possible to recognize the specification.

The semantics of the languages are not formally specified in a way that makes a formal proof of the semantical equivalence possible. The first correctness requirement of the translation can therefore only be argued informally. The second requirement is to ensure that it is possible to integrate a part of a system which is specified and translated using a tool, and other parts of a system which are implemented without the use of a tool.

Requirements of Translator

1. The translator must translate a subset of RSL into Java according to the translation defined.

2. The translator must provide extensibility.

The requirement of being open to extensions is set to ensure that if a translation for a larger subset of RSL is defined, then it should be easy to extend the translator to translate this new subset.

1.3 Related Work

There are a number of tools developed for RSL [15, 10], including a type–checker, a pretty–printer and translators from RSL into a number of different programming languages. Most of these tools have been developed using the Gentle Compiler Construction System [17] or Cornell Syntesizer Generator [16]. The type–checker has been used in this project to ensure that specifications have the correct syntax before they are translated into Java.

1.4 Prerequisites

This report has a number of prerequisites for reading it.

1. A knowledge of RSL.

2. A knowledge of Java.

3. A basic idea of how to develop a language processor.

The meaning and use of the different constructs in the two languages are not explained. It is assumed that the reader is familiar with both the meaning and the use of the constructs. The process of developing a language processor is explained but some knowledge of the key concepts is expected.

1.5 Report Overview

The remainder of the report is structured as follows. Chapter 2 develops a general idea of how to define a translation from the specification language RSL into the programming language Java. Based on the ideas in Chapter 2 the development strategies for a translator are discussed in Chapter 3, which also outlines some of the technical issues involved in developing a translation between the languages. Chapter 4 and 5 describes the actual implementation of the translator. Chapter 6 describes the test schemes used for testing the tool developed in this project. Chapter 7 gives suggestions for extensions of the work done in this project. Finally, Chapter 8 summarizes the achievements of this work and evaluates these.

Chapter 2

Informal Description of Translation

This chapter presents an informal description of the translation from RSL into Java. The discussion will go through the constructs in RSL. For each of the constructs a discussion of the possible translations considered are given, as well as a description of the translation chosen.

The chapter starts with some considerations concerning a number of issues which are not related to a specific construct in RSL, followed by a section dealing with the top–level structures of RSL. Finally, there is a section covering each kind of declarations in RSL.

2.1 Translation from RSL into Java

Even though it is possible to find many correspondences between RSL and Java and to define translations for many of the constructs in RSL there are some issues, that do not belong to any individual construct in RSL, but which are of a more general nature. These general issues are covered in the following.

2.1.1 Identifiers in RSL and Identifiers in Java

In RSL, identifiers are used in numerous places e.g. for naming types and values. In Java, there are also identifiers which are used for naming fields, methods and classes. In the translation from RSL into Java it would be an advantage for the recognizability between the specification and the translation, if the identifiers in RSL could be reused in the translation. Two things should be kept in mind:

1. Differences in the character sets allowed for identifiers.
2. Differences in where the same identifier may be used again.

In RSL, an identifier must start with an ASCII letter or a greek letter, and it may contain ASCII letters, greek letters, digits, _ and ‘’. An RSL identifier may not start with _. Identifiers starting with _ are permitted in Java and this can be used to avoid name clashes when defining auxiliary identifiers in Java. Identifiers in RSL cannot be reused in Java without consideration of what to do with the characters which are allowed in RSL identifiers, but not in Java. To make the translation easy and to make it easier to see a correspondence between the identifiers in the specification and in the translation, only identifiers using the English character set, digits, and underscore are considered in this project.

The scope of identifiers are different in Java compared to RSL. The structure of the two languages are completely different. The translation of types from RSL into Java is performed using classes. Two classes may not be named identically within a package in Java, therefore there cannot be two types using the same name in the specification even though they belong to different scopes in RSL. In this work, reuse of identifiers is not considered.

2.2 Top Level Structure of RSL

The top level structure of an RSL specification is a module. A module may contain an entire specification as well as other modules, and it is therefore possible to decompose a large specification into smaller comprehensible and reusable units. There exist two kinds of modules, namely *objects* and *schemes*. Both of these structures rely on the concept: A class expression. This concept is presented in the following and afterwards the two kinds of modules are discussed.

2.2.1 Class Expressions

The most fundamental form of a class expression is a *basic class expression*. There are a number of operators for manipulating a class expression, but the only way to create a class expression is by a basic class expression. A basic class expression contains a list of declarations. In Example 2.1 a basic class expression containing a value declaration and an axiom declaration is shown. The meaning of a class expression is essentially a set of models. The reason that it is a set of models is that it is possible to under–specify the declarations. The class expression presented in Example 2.1 contains two

models, which satisfy the declarations, namely one where i is bound to 1 and one where i is bound to 2.

Example 2.1 An under–specified basic class expression in RSL.

```
class
   value i : Int
   axiom i = 1 ∨ i = 2
end
```

A class expression may be named and instantiated by using objects and schemes.

2.2.2 Objects and Schemes

An object is essentially a named model chosen from a class of models represented by some class expression [11]. A scheme, on the other hand, is a naming of a class expression. One could say that an object is an instance of a class expression. The concept of a scheme, i.e. a naming of a class, is necessary in order to be able to manipulate class expressions without having to write the entire class expression multiple times.

The idea of grouping a number of values, variables and functions can also be found in Java, namely the *class* construct in Java. A class in Java is able to hold values, variables and methods and it is therefore chosen as translation of the basic class expression. In Java, a class must be given a name. In RSL, a class expression is not named, but a scheme is a named class expression, and therefore, the translation of a scheme in RSL is a class in Java. The use of operators on a class expression does not change the basic idea that a scheme is translated as a class. A scheme may be parameterized allowing for a specification of a more general solution and then concretized in instantiations. The use of parameterization of schemes complicates the process, but this does not change the idea, that a scheme is a named class expression, and therefore should be translated as some sort of class in Java. A discussion of parameterized schemes can be found in Section 2.2.4

An object can be considered as an instance of a class expression in RSL. An object is declared by the entire class expression after the name of the object. Two forms of declaration of an object are shown in Example 2.2.

An object in RSL may be referenced by other modules. In Example 2.3, a third object referencing the objects (LIST1, LIST2) from Example 2.2 is shown.

Example 2.2 Example of declarations of objects in RSL.

```
scheme LIST_SCHEME =
  class
    variable list : Int*
    value
      empty : Unit → write list Unit
      empty() ≡ list := ⟨⟩,
      is_empty : Unit → read list Bool
      is_empty() ≡ list = ⟨⟩,
      add : Int → write list Unit,
      add(i) ≡ list := ⟨i⟩ ⌢ list,
      head : Unit ~→ read list Int
      head() ≡ hd list
      pre ~is_empty(),
      tail : Unit ~→ write list Unit
      tail() ≡ list := tl list
      pre ~is_empty()
  end
object
  LIST1 : LIST_SCHEME,
  LIST2 : LIST_SCHEME
/*They could also be declared as*/
object
  LIST1 : class ... content of class expression in LIST_SCHEME ... end
  LIST2 : class ... content of class expression in LIST_SCHEME ... end
```

Example 2.3 Example of use of an object within another object.

```
object LIST_APPLY :
  class
    value
      apply : (Int → Int) → read LIST1.list
      apply(f) ≡
        if ~LIST1.is_empty() then
          let first = LIST2.head() in
            LIST2.tail() ; apply(f) ; LIST2.add(f(first))
          end
        end
  end
```

The two examples of declarations of objects presented give two possible translations in Java:

1. Translate each object and scheme as a class of its own with static variables and static methods.

2. Translate the scheme LIST_SCHEME as a class and let the two objects LIST1 and LIST2 be translated as instances of the class which results of the translation of LIST_SCHEME if the first form of declaration of objects is used. LIST_APPLY should then be translated as an instance of another class and the same goes for LIST1 and LIST2 if the second form of declaration of objects is used.

As described in Section 2.1.1 an identifier in RSL cannot start with an underscore character this can be used to create a class for the object LIST_APPLY and then let LIST_APPLY be an instance of this class.

Section 2.2.6 discusses the advantages and disadvanteges of the two possible solutions.

2.2.3 Operators on Class Expression

In RSL, there are three ways of manipulating a class expression:

1. Extension.

2. Hiding.

3. Renaming.

Common for these three operators are that they all result in a new class expression, which may be manipulated further.

Extension

The idea of extension in RSL is to build a class expression in successive steps, adding new properties at each step. The form of an extending class expression is:

extend base_class **with** extending_class

The extending class expression may use all the declarations defined in the base class expression. In fact, the extending class expression is equivalent to a basic class expression containing all the declarations of both `base_class` and `extending_class`. Both `base_class` and `extending_class` may be any kind

of class expression including an identifier of another scheme, this is called a scheme instantiation. The most common use of an extending class expression is to let the base class be an identifier of a scheme defined elsewhere, and let `extending_class` be a basic class expression containing declarations of the new properties.

The way the extension is defined in RSL gives two possibilities for translation into Java:

1. Use the fact that an extending class expression in RSL is equivalent to a basic class expression, and translate the basic class expression
2. Use the possibility in Java to extend one class with another.

Both of these suggestions have advantages and disadvantages. The disadvantage of the first suggestion is, that the Java source code generated is not divided into several classes. It is harder to read and not as close to the idea in the specification, which is to have the system divided into several smaller units. The advantage of the first suggestion is that it is easy to deal with since all that is needed is a translation of all the declarations of the two class expressions. The advantage of the second suggestion is that the idea of the specification to split the details of the specification into smaller units is preserved. This property is kept by creating one class in Java per class expression in RSL, and let the classes created extend each other in the right order, as shown in Example 2.4. The disadvantage of the second suggestion is that it is more complicated to deal with than one large basic class expression.

The second suggestion is chosen because it preserves the idea of dividing a specification into several schemes, and keeping this as several pieces in Java.

Hiding

The purpose of the hide operator in RSL is to hide identifiers used inside a class expression from modules using the class expression either by extension or by instantiation. The form of a hiding class expression is:

hide id **in** class_expression

In Java, identifiers must be declared public to be accessible from classes in other packages. In RSL, all declarations are accessible by other modules unless they are explicitly hidden, therefore, as default all fields and methods are declared *public* in the Java source code generated. When the hide expression is used the access modifier of a field or method is changed to *protected* to disallow access, as shown in Examples 2.5 and 2.6. As stated later type definitions should be translated as classes in Java. These classes are by default

Example 2.4 Using the extend feature in Java for extension in RSL.

```
scheme LIST_STATE =
  class
    variable list : Int*
  end

scheme LIST_OPERATIONS =
  extend LIST_STATE with
  class
    value
      is_empty : Unit → read list Bool
      is_empty() ≡ list = ⟨⟩
  end
```

```
public class LIST_STATE {
    public static RSLListDefault<Integer> list;
    //RSLListDefault is explained in Section 2.3.2.
}

public class LIST_OPERATIONS extends LIST_STATE {
    public static boolean is_empty() {
        return list.equals(new RSLListDefault<Integer>());
    }
}
```

declared *public* and put into a file of their own. If a type is to be hidden, the corresponding class should be declared *private*. A *private* class must be declared within the class that uses it. This presents a problem because in a specification more than one type definition may use a hidden type definition as a type of a component. When these type definitions are translated as different *public* classes in different files, then there is no place where the *private* class corresponding to the hidden type can be declared so that both *public* classes can access it. Hiding of types should therefore be disallowed in the translation.

Example 2.5 Translation of a scheme not hiding the variable.

scheme LIST =
class
  variable
    list : **Int***
end

```
public class LIST {
    public static RSLListDefault<Integer> list;
}
```

Example 2.6 Translation of a scheme hiding the variable.

scheme ENCAPSULATED_LIST =
hide list **in**
class
  variable
    list : **Int***
end

```
public class ENCAPSULATED_LIST {
    protected static RSLListDefault<Integer> list;
}
```

Renaming

The purpose of the renaming in RSL is to rename an identifier in relation to other modules. The form of a renaming class expression is:

use id_1 **for** $\text{id}_2, \ldots, \text{id}_m$ **for** id_n **in** class_expression

In Java, there is no concept of renaming identifiers, therefore the renaming must be done before the specification is translated. In RSL a renaming class expression can be expanded into a basic class expression simply by renaming all the identifiers in the class expression according to the list of renaming pairs as shown in Example 2.7. In the translation into Java this expansion should be used.

Example 2.7 Renaming class expression.

```
scheme STACK_SCHEME =
use stack for list in
LIST_STATE
```

Is equivalent to:

```
scheme STACK_SCHEME =
class
   variable
      stack : Int*
end
```

2.2.4 Parameterized Schemes

This project does not define an exact translation for parameterized schemes in RSL. This section discusses some of the issues in the definition of a translation for parameterized schemes. The discussion is included to ensure that the translation of objects and classes defined in this work does not present problems in later extensions of the project.

RSL allows for a wide variety of parameterization of schemes defined in a specification. A scheme is parameterized with objects. One possible use of this is a scheme defining a list, in which the type of the elements of the list has been moved to a parameter of the scheme. The scheme is shown in Example 2.8.

This concept of defining a general class, which can later be instantiated with a specific type is also known in programming languages. In C++ it is known as templates. In Java, the concept has recently been added in version 1.5 under the name generics. The parameterized scheme presented

Example 2.8 Parameterized list in RSL.

```
scheme PARAM_LIST(E: class type Elem end) =
class
   variable
      list : E.Elem*
      ⋮
end
```

Example 2.9 Translation of a parameterized list in Java.

```
public class PARAM_LIST<E> {

    public RSLList<E> list;

    ...
}
```

in Example 2.8 could in Java be translated to the generic class shown in Example 2.9.

Generic methods must be dynamic in Java. The reason for this is that at the time of invocation of the method, the generic type must be known. In Java, the only way to declare the type of a generic class is to instantiate an object of the class with the generic type as type–parameter. A static method in Java does not require an instantiation of an object and the generic type can therefore not be determined. This is the reason that only dynamic methods are allowed to be generic.

Parameterization in RSL may be done with other kinds of declarations than type declarations since the parameterization is based on objects, which may be instances of class expressions containing any kind of declarations. The scheme parameterization in RSL is a way of writing a more general specification, when a parameterized scheme is used either in an instantiation of an object or in a class expression of another scheme, it must be instantiated with an object. A parameterized scheme instantiated with an object can be expanded to a basic class expression.

This gives two possibilities for translation of an instantiation of a parameterized scheme:

1. Rewrite parameterized schemes as basic class expressions and translate the basic class expressions.

2. Define a number of translations depending on the kind of parameterization.

The first suggestion is obiviously the most simple solution, but it has the drawback that it creates one large class rather than dividing the properties between several entities which is the point of the parameterized scheme. An example of an instantiated parameterized scheme and the equivalent expanded class expression is shown in Example 2.10 and Example 2.11.

Example 2.10 Instantiation of parameterized scheme.

```
scheme SIZE =
class
  value
    size : Nat
end

scheme SIZED_INTLIST(S : SIZE) =
class
  variable
    list : Int*
  value
    empty : Unit → write list Unit
    empty() ≡ list := ⟨⟩,
    add : Int → write list Unit
    add(e) ≡ list := ⟨e⟩ ⌢ list
      pre len list < S.size
end

object S :
class
  value
    size : Nat = 7
end

object USESIZEDLIST : SIZED_INTLIST(S)
```

The second suggestion is much more complex to translate, but also provides a solution which is more in line with the idea of the specification. First of all, this project only considers explicit specifications, therefore the use of

Example 2.11 Expanded instantiated parameterized scheme equivalent.

```
object USESIZEDLISTEXPANDED :
class
   variable
      list : Int*
   value
      empty : Unit → write list Unit
      empty() ≡ list := ⟨⟩,
      add : Int → write list Unit
      add(e) ≡ list := ⟨e⟩ ⌢ list
         pre len list < 7
end
```

parameterization to combine axioms are not considered. Only parameterization with variables, values and types are considered, parameterization with channels are part of specification of parallel systems and is not considered. However, the channel concept has some similarities with channels in Java, which may be placed as a field in a class, a discussion of possible translation of channels can be found in Section 7.3.2. Therefore, the translation of parameterization with variables and values could also be considered for channels.

As shown later, type definitions are translated as one or more classes, the translation of a parameterized scheme using types as a parameter could therefore be translated using generics classes in Java as presented in Example 2.9.

Parameterization with variables and values presents some other challenges. Example 2.10 shows a scheme SIZED_INTLIST which is a specification of a list of limited size. The size of the list is put as a parameter to the scheme to allow different sizes of lists. The challenge of the translation of these schemes and objects is to ensure that it is possible to create lists of different sizes which may be referenced from other modules. It should noted that a value in RSL is constant, i.e., it cannot be changed, therefore, the translation should ensure that this is also the case. The translation of a value in the parameter of a scheme could be translated as an argument to the constructor of the class created and kept in the class as a private finalized field to ensure that it cannot be changed. The same translation could be used for variables except that the field in Java should not be declared **final** so that methods could manipulate the translation of the variable. Objects

used in the instantiation of a parameterized are not translated as objects are elsewhere. An example of the translation of the parameterized scheme in Example 2.10 is presented in Example 2.12.

Example 2.12 Translation of parameterized scheme presented in Example 2.10.

```
public class SIZED_INTLIST {
    private final int size;
    public RSLList<Integer> list;

    public SIZED_INTLIST(int size) {
        this.size = size;
    }

    public void empty() {
        list = new RSLListDefault<Integer>();
    }

    public void add(int e) {
        assert list.len() < size;
        list = (new RSLListDefault<Integer>(e))
            .concat(list);
    }
}
```

2.2.5 Object Arrays

This project does not consider a translation of object arrays in RSL. The purpose of the discussion in this section is to ensure that the selection of translation for schemes and objects does not become prohibitive for later extensions allowing the use of object arrays in a specification.

In RSL, it is possible to group a number of objects of the same type into an object array. The objects do not have to be named themselves, but may be referenced by an index to the array. The concept seems fairly correlated to an array of objects in Java. There are a number of differences between object arrays in RSL and arrays in Java. In RSL, an array may be indexed using any type including **Int**, which can be infinite, making the object array infinite in size. In Java, an array has a maximum size based on the limit of *int*, which is used for indexing. Furthermore, arrays in Java may only be indexed using integers and not other types. Therefore, an object array in RSL cannot be translated directly as an array in Java.

In order to translate an object array in RSL into an array in Java, objects in RSL must be translated as instances of classes in Java. Furthermore, a number of conditions of an object array must be met:

1. The typing of the object array in RSL must be finite.
2. It must be possible to calculate the number of elements in the array.
3. The number of elements must not exceed the total number of elements allowed in an array in Java.

If the conditions presented above are met, then an object array in RSL could be translated as an array in Java. An object array declaration and a possible translation is shown in Example 2.13.

Example 2.13 Translation of an object array declaration.

object
O[f : Finite_Typing] : SCHEME
type
Finite_Typing

Is translated as:

```
SCHEME[] O = new SCHEME[/* Calculated size of Finite_Typing */];
private static int getIndex(Finite_Typing ft) {...}
```

2.2.6 Overview of translation of top–level structures

This section presents an overview of the translations of the top–level structures in RSL. It summarizes the choices made in the previous sections.

Unparameterized Schemes

The form of an unparameterized scheme is:

scheme id = ce

where `ce` is a class expression.
The translation in Java is:

```
class ID { CE }
```

ID is the translation of id
CE is the translation of ce

An unparameterized scheme which is not used in instantiations of objects is translated using static methods to make it possible to create a library which does not need an instantiation of an object in Java.

Basic Class Expressions

The form of a basic class expression is:

class
⋮
Constituent declarations
⋮
end

The translation of a basic class expression is a translation of each of its constituent declarations.

1. Translation of type declarations: see Section 2.3.
2. Translation of value declarations: see Section 2.4.
3. Translation of variables is not covered in this work. Suggestion for a translation is given in Section 7.3.1.
4. Translation of channels is not covered in this work. Suggestion for a translation is given in Section 7.3.2.
5. Translation of axioms is not covered in this work.

Extending Class Expressions

Extending class expressions having the form:

extend ce **with** ce_2

where `ce` and ce_2 are class expressions. ce_2 must be a basic class expression. If `ce` is a scheme instantiation then the translation is:

class ID **extends** CE {/* *Translation of declarations of* ce_2 */}

ID is determined from the context. It is either the translation of the name of the scheme containing the extending class expression or determined from the identifier of the object containing the class expression. If `ce` is not a scheme instantiation then the translation is done as if `ce` had the form:

scheme id = ce

where `id` is an auxiliary identifier created in the translation.
The translation is then the same as if `ce` is a scheme instantiation.

Renaming Class Expressions

Renaming class expressions having the form:

use id_{11} **for** id_{12}, ..., id_{n1} **for** id_{n2} **in** ce

where `ce` is a class expression.
This form can be unfolded to a basic class expression[1] by substituting $\texttt{id}_{i1}$ for $\texttt{id}_{i2}$ for $i \in \{1, \ldots, n\}$ in `ce`.

There are no possibilities for renaming identifiers in Java, therefore, the translation is a translation of the unfolded class expression.

Hiding Class Expressions

Hiding class expression having the form:

hide id-list **in** ce

The idea of the translation into Java is to translate the class expression `ce` and afterwards traverse the translated Java and change the modifiers according to the `id`–list. Hiding of types are not covered in this work. Hiding of values and the suggested translation of variables should be done by replacing the **public** modifier with the **protected** modifier.

Scheme Instantiations

The translation of scheme instantiation should be done by unfolding the class expression and translate that, except when dealing with extending class expressions which was explained above.

[1] This is only possible if there are no hidings.

Parameterized Schemes

A parameterized scheme having the following form:

$s(O : ce) = ce_2$

where `ce` is a basic class expression and only contains type declarations, explicit value definitions and variables.
Translation in Java:

```
S<Ta,...,Tz> {
  private [final] V1 _v1;
  ⋮
  private [final] Vn _vn;
  S(V1 _v1,..., Vn _vn) {
    this._v1 = _v1;
    ⋮
    this._vn = _vn;
  }
  /* Translation of ce2 */
}
```

S is the translation of the name s.
T_a to T_z is the translation of the names of the type declarations of `ce`.
V_1 to V_n is the translation of the types of the values and variable declarations of `ce`
[final] is used in a translation of value declarations and not in a translation of variable declarations.

Translation of a parameterized scheme is a class, the nature of the class in Java depends on the kind of parameterization. Parameterization with types are translated using the generic feature of Java. Parameterization with values and variables are done by translating them as fields and initialize them in the constructor.

Objects

The translation of objects depends on the nature of the class expression included in the object declaration.
Objects declared with a scheme instantiation:

object
$O : id_s$

Is translated as:

```
Id_s O = new Id_s();
```

Id_s is the translation of id_s.

Objects declared with other class expressions than scheme instantiations:

O : ce

Is translated as:

```
class _Id {/* Translation of ce*/}
_Id O = new _Id();
```

_Id is a created identifier from id.

2.3 Types in RSL

In RSL, there are two kinds of types: simple types and complex types, and additionally there are a number of type definitions.

The types and type definitions are described in the following sections along with the chosen translation in Java and a discussion of alternatives considered. First the simple types are described, then the complex types and finally the type definitions are described.

2.3.1 Built–in Types

The simple types are **Bool**, **Int**, **Nat**, **Real**, **Char**, **Text**, and **Unit**. For all these built–in types two operators for comparing values of the type are defined, namely = and $\neq$. All these types in RSL must be represented in some way in Java. In Java, there are also a number of built-in types for representing truth values as well as numerical values, characters and texts. Two suggestions for translation of the built–in types are given:

1. Represent the built–in types of RSL, using primitive types and library classes in Java.

2. Implement a collection of classes in Java for representing the built–in types of RSL.

Both of these suggestions have a number of advantages and disadvantages.

Using Primitive Types and Library Classes in Java

The first advantage of this suggestion is that value literals in RSL can be translated as value literals in Java, thereby avoiding having to create an object for each value literal in RSL. The second advantage is that expressions using the standard arithmetic operators can be translated using infix expressions in Java, rather than method invocations. The reason for this is that the built–in operators in Java cannot be overloaded, and therefore the only expressions allowed to use them are those where the operands are of primitive types. Both these advantages makes it easier to recognize the specification in the translation. A third important advantage of using primitive types for representing the built–in types of RSL is an efficiency issue. It is much more efficient to represent a numerical value in Java using a primitive type than an instance of a class.

The main disadvantage of this solution is that the types for representing numerical values in Java are limited in their size, whereas the numerical types of RSL are infinite, therefore some mechanism must be provided for handling the limit of a type in Java.

The reason that the suggestion is a combination of both primitive types and library classes in Java is that the primitive types cannot be used in collections in Java. Therefore, the translation needs to use the wrapper classes of the primitives types, when dealing with collections in Java.

Using a Collection of Classes Implemented

The main advantage of this suggestion is that each of the types in RSL are only represented as one type in Java and not as a combination of a primitive type and a wrapper class. Another advantage is that the problem of representing infinitely large values of RSL can be handled inside the classes implemented. It should be noted that it is not possible to represent values of infinite size or precision on a machine with a limited storage.

The main disadvantage is that it is not possible to overload the standard operators in Java, therefore all infix operators must be translated as methods rather than operators in Java, which makes it harder to recognize a specification in the translation of a specification.

Choice of representation of built–in types of RSL

Both of the presented suggestions have advantages and disadvantages. In this work the first suggestion have been chosen, because it is the most intuitive solution. There are several possible solutions to the problem with the sizes of the types in Java.

1. Let the user decide how to translate each of the built–in types.

2. Let the user decide the translation of each use of a built–in type via meta data in the specification.

3. Use the widest type to reduce the number of times a limit causes troubles.

4. Decide on a type representation in Java, which suits most situations.

The first and third of the four solutions have a problem in case of selecting a large type like *BigInteger* for representing **Int** and then having a for–loop construction with values 1 to 5. In this case the selection of *BigInteger* would be very inefficient, but it may be needed in other parts of a specification. The second solution, where different types may be used, presents a problem because some type casts may be needed when assigning a value of a wider type to a narrower one. Type casting should only be performed with great care of a programmer since the value being type cast may be too large to fit within the new type. The fourth solution was chosen for this project, but with the requirement, that it should be relatively easy to change the type in the tool developed.

Type Bool

The type **Bool** in RSL represents the boolean values, **true** or **false**. In Java, there is a type containing the truth values namely *boolean* or wrapped as an object *Boolean*. The primitive value *boolean* and the wrapper class *Boolean* in Java were chosen to represent the RSL type **Bool**.

Two operators have been defined and a number of connectives for values of the type **Bool**. They are presented in Table 2.1 along with their translation into Java.

RSL	**Translation into Java**
b1 = b2	b1 == b2 or b1.equals(b2)
b1 ≠ b2	b1 != b2 or !b1.equals(b2)
∼ b1	!b1
b1 ∧ b2	b1 && b2
b1 ∨ b2	b1 || b2
b1 ⇒ b2	**if**(b1) b2 **else true**

Table 2.1: Operators and connectives for type **Bool**

The use of == or equals and != or !equals depends on whether the type of the operands involved are of the wrapper class, *Boolean*, or the primitive type *boolean*. == and != are defined for both objects and the primitive types. It is therefore necessary to determine, whether to use the operators or the methods. The operators == and != for objects determine whether or not it is the same object, and not whether or not the value of the object is the same. For the connectives this is not a problem since these are not defined for objects and Java can therefore automatically unwrap the objects before using the operator.

Type Int

The type **Int** in RSL represents the type containing integer values in the range ..., -2, -1, 0, 1, 2, ... In Java, there are several types for representing integer values depending on the range needed. The Java types for representing integer values are shown in Table 2.2 along with their ranges.

Type	Range
`byte`	-128 to 127
`short`	-32,768 to 32,767
`int`	-2,147,483,648 to 2,147,438,647
`long`	-9,223,372,036,854,775,808 to 9,223,372,036,854,775,807
`BigInteger`	no range [a]

[a] No limit but in practice limited by the size of the memory of the machine.

Table 2.2: Overview of Java types for representing integer values.

This project will use *int* and the wrapper class *Integer* for representing the RSL type **Int**. A number of operators have been defined for values of the RSL type **Int**. These are shown in Table 2.3 along with their translation in Java.

The choice of whether to use == or equals as well as their negated counterparts is the same as for type **Bool**.

The integer division in RSL returns the whole number of times the first operand goes into the second. The same is true for the division operator / in Java. The integer remainder operator \ in RSL handles negative values the same way the Java modulo operator % does, by returning the absolute value of the remainder with the sign of the first operand.

RSL	Translation in Java
i = j	i == j or i.equals(j)
i ≠ j	i != j or !i.equals(j)
i > j	i > j
i ≥ j	i >= j
i < j	i < j
i ≤ j	i <= j
i + j	i + j
i − j	i − j
i ∗ j	i ∗ j
i / j	i / j
i \ j	i % j
i ↑ j	(**int**) Math.pow(i, j)
real i	(**double**)i

Table 2.3: Operators for the type **Int**

Type Nat

The type **Nat** in RSL represents the type containing the natural numbers, which are the same as the values in **Int**, except that **Nat** contains only the positive values and zero. The operators for **Nat** are exactly the same as for **Int**. The **Nat** type in RSL is actually a subtype of **Int**, and the handling of subtypes is discussed in Section 2.3.4.

Type Real

The type **Real** in RSL represents all the real numbers and may have values like . . . , -2,3, 0.0, 5.7, . . . and with an infinite number of decimals i.e. infinite precission. In Java real numbers are represented by a number of types. Each of them are shown in Table 2.4 along with their ranges.

Type	Range
`float`	3.8×10^{-38} to 3.8×10^{38}
`double`	1.7×10^{-308} to 1.7×10^{308}
`BigDecimal`	no range [a]

[a] Based on the BigInteger and has the same limitations.

Table 2.4: Overview of Java types for representing real values.

The primitive type *double* and the wrapper class *Double* will be used to represent the RSL type **Real** in this project. The operators on values of the

type **Real** are the same as for **Int**. The only exception is that the ↑ returns a **Real** instead of an **Int** and the translation is therefore Math.pow(i, j). The standard arithmetic operators and relational operators in Java are overloaded and also works for values of type *double*, therefore the translations are the same as for **Int**. The conversion operator **real** is only defined for type **Int**, and therefore a translation is not defined. The last built–in operator defined for **Real** is an operator for converting a **Real** to an **Int**. This operator is called **int** and like the operator **real** it is translated as type casting: (**int**) r where r is of type double. Both the RSL operator **int** and type casting (**int**) returns the integer closest towards zero, i.e. truncation.

Type Char

The type **Char** represents individual characters in RSL. In Java, there is also a type for representing single characters namely *char*. Therefore, the translation of type **Char** in RSL is *char* and *Character* in Java. The translation of the two operators for equality and inequality is the same as for the other built–in types described. No other operators have been defined for the RSL type **Char**. The character set allowed in RSL contains the English alphabet, digits and a number of graphics characters. The graphical characters in RSL are not represented in the same way as in Java, therefore a translation between the two character sets is needed. The treatment of special characters in RSL are not considered in this work, but it would only present a minor extension.

Type Text

The type **Text** in RSL represents strings of characters. In Java, there is also a type for representing strings of characters and that is the class *String*. *String* is therefore chosen as translation of type **Text**. In RSL, **Text** is defined as a list of characters and therefore the standard list operators are also valid for values of type **Text**. This leads to the idea of translating **Text** as a list of characters in Java. This would, however, lead to a very inefficient solution since each character would have to be represented by an object, and the possibility of using the standard notation for *String* in Java would be lost. The standard list operators do not have a direct translation in Java. They are translated using the methods in the class *String*.

The standard list operators for **Text** are translated as shown in Table 2.5.

RSL	Translation in Java
⌢	String concat(String str)
hd	**char** charAt(0)
tl	String substring(1)
len	**int** length()
elems	**new** RSLSetDefault<Character>(s.toCharArray())[a]
inds	**new** RSLSetDefault<Integer>.range(1, s.length())[a]

[a] For a description of RSLSetDefault please see Section 2.3.2.

Table 2.5: Overview of translations of **Text** operations in Java

Type Unit

The type **Unit** in RSL represent a single empty value. In RSL, it is often used in the type expression of a function for either representing, that the function has no return value, or that it does not take any arguments. In Java, a method with no return value uses the keyword *void*. A method in Java that does not have any arguments is just written with empty parentheses after the method identifier. In RSL the two operators for equality and inequality also works for **Unit**. The use of the equality operator on two expressions evaluating to **Unit** is true, while use of the inequality operator is false. To obtain the same properties in Java, a special type for representing a single value should be implemented, since values of type void are not allowed in Java.

Translations of the built–in RSL types have been summarized in Table 2.6.

RSL	Java
Bool	**boolean** or Boolean
Int	**int** or Integer
Nat	No translation.
Real	**double** or Double
Char	**char** or Character
Text	String
Unit	No translation. Functions should use the keyword **void** and ().

Table 2.6: Summary of translation of built–in types in RSL.

2.3.2 Complex Types

There are several complex types in RSL, namely: product, function, list, map and set. Common for the complex types are that they involve other types, which may be: Simple types, complex types, or names of type definitions. Lists, sets and maps in RSL may both be finite and infinite, but due to the limitations of Java, this work only considers the finite versions. Structures of infinite size are not well suited for an executable program. However, it should be noted, that there are a number of special cases in which infinite lists, sets and maps can be evaluated, these special cases are not considered in this project. The three complex types list, set and map have direct counterparts in Java in form of a number of interfaces extending the general *collection* interface. The two complex types, product and function, do not have any direct counterparts in Java.

Product Types

An RSL product is defined as a finite ordered collection of possibly different types [11]. Product type expression are of the form:

$\text{type\_expr}_1 \times \ldots \times \text{type\_expr}_n$

Values of a product type of this form is a tuple of length n:

$(\text{value\_expr}_1, \ldots, \text{value\_expr}_n)$

value_expr$_i$ is a value of type *type_expr*$_i$.

The only way in Java to create a new type is to create a class. Therefore a product type expression in RSL is translated as a class in Java. Each *type_expr*$_i$ is translated as a public field in the class with an identifier "_v[i]" and the type of the field is the translation of the *type_expr*$_i$.

There are no operations defined on products except for $=$ and $\neq$ which should be translated as p_1.equals(p_2) and !p_1.equals(p_2). The equals method must call the equals method for all subparts of reference types and use an infix expression with the == operator for all subparts of primitive types. An example of the translation of a product type is shown in Example 2.14.

Function Types

In RSL, a function is a value like any other value. This means that functions may be used as parameters to other functions. It is possible to specify higher order functions as well as to compose functions from other functions. The

Example 2.14 Translation of a product.

SYSTEM_OF_COORDINATES =
class
  value
    origo : **Unit** → **Real** × **Real**
    origo() ≡ (0.0, 0.0)
end

```
public class _C {
    public double _v1;
    public double _v2;

    public _C(double _v1, double _v2) {
        this._v1 = _v1;
        this._v2 = _v2;
    }

    public boolean equals(Object o) {
        if(o instanceof _C) {
            return ((this._v1 == o._v1) &&
                    (this._v2 == o._v2));
        }
        return false;
    }
}

public class SYSTEM_OF_COORDINATES {

    public static _C origo() {
        return new _C(0.0, 0.0);
    }

}
```

idea of using a function as a parameter to another function has no direct counterpart in Java. In Java, methods represent a special type, and it is not possible to create values of that type. There exist a class *Method* in Java, and an instance of the class *Class* contains a collection of these methods. However, it is not possible to modify the collection of methods and it is not possible to create an instance of the class *Method*.

RSL provides two constructors, $\rightarrow$ and $\xrightarrow{\sim}$, for building function types. Only the former constructor is considered, it constructs total function, whereas the latter constructs partial functions, a kind of under specification which is not considered in this project.

In C or C++ the use of functions as parameters could be solved using pointers to functions, but this is not possible in Java. One possible solution is to use an interface containing a method called action, and let different values of function types in RSL be represented as an object implementing the interface. An example of the possible implementation in Java is shown in Example 2.15

The function expression, which is taken as parameter to the function `twice`, is translated as an interface containing one method action which has the same signature as the function type expression of the parameter. The first test case presented in the example is not very useful, but the result of calling `twice` with one parameter could be used as input for another higher order function taking a function from **Int** to **Int** as parameter.

The translation of an uncurried version of the function `twice` could be translated using a similar scheme, which is shown in Example 2.16.

List Types

A list in RSL is a sequence of values of the same type [11]. The concept of a list can also be found in Java. A list in Java is represented by the interface *List*. The interface *List* in Java defines a number of methods for manipulating a list. When comparing the methods in the *List* interface and the operators on lists in RSL, one can see, that most of the operators on lists exists as methods in the Java interface even though the names and exact use are a little different.

An interface, *RSLList*, has been implemented along with an implementing class, *RSLListDefault*. The source code for *RSLList* can be found in Appendix E.2.1 and the source code for *RSLListDefault* can be found in Appendix E.2.2. The combination of an interface and an implementing class allows others to develop a different implementation of a representation for lists.

The interface defines methods, which correspond directly to the operators

Example 2.15 Defining a function using an interface.

value
twice : (**Int** → **Int**) → (**Int** → **Int**)
twice(f, i) ≡ f(f(i))
test_case
[t1] twice(λ i : **Int** • i + 1),
[t2] twice(λ i : **Int** • i − 1)(1)

```
interface IntXInt {
    public int action(int _v1);
}

public static IntXInt twice(final IntXInt f) {
    return new IntXInt() {public int action(int i){
        return f.action(f.action(i));}};
}

public static void main(String[] args) {
    System.out.println("[t1]: " +
        twice(new IntXInt() {
                public int action(int i) {return i + 1;}}));
    System.out.println("[t2]: " +
        twice(new IntXInt() {
                public int action(int i) {return i - 1;}}).
                    action(1));
}
```

value
twice : (**Int** → **Int**) × **Int** → **Int**
twice(f, i) ≡ f(f(i))
test_case
[t1] twice(λ i : **Int** • i + 2, 3)

```
interface IntXInt {      public int action(int _v1); }

public static int twice(final IntXInt f, int i) {
    return f.action(f.action(i));
}

public static void main(String[] args) {
    System.out.println("[t1]: " +
       twice(new IntXInt() {
                public int action(int i) {return i + 2;}},
             3));
}
```

on lists in RSL. The implementing class is based on a collection implementing the *List* interface. New implementations of the interface must at least contain the same constructors as *RSLListDefault*. The constructors are not specified in the interface, because this is not allowed in Java.

The translation from RSL into Java is as follows:
RSL:
t*
Java:
RSLListDefault<T>, where T is the translation of t[2].

As stated previously infinite lists have been left out. In RSL, a new list can be created in three ways; either by enumerating the elements, specifying an interval, or by a comprehended list expression. The translation of the two first methods for creating lists is straightforward. *RSLListDefault* contains a constructor taking an array which holds the enumerated elements, and a constructor taking two integers for specifying an interval. The comprehended list expression consists of three parts: a list, an expression which must be

[2]The notation <T> is standard in Java 1.5 for the generic type of the class. Please see Section 4.1 on page 105 for an explanation of the new generic feature of Java 1.5.

applied for each element in the list before inserting it into the new list, and an optional condition which an element from the old list must fulfill, in order to be inserted into the new list. This form of list creation is implemented as a method *listComp* in the RSLList interface taking two parameters: an *RSLExpression* and an optional *Testable*. *RSLExpression* represents the expression, which must be applied for each element before it is inserted into the new list. *RSLExpression* is an generic interface and in order to use it, one must create a class implementing the generic method *action*. *Testable* represents the condition which must be fulfilled for each element to be inserted into the new list. *Testable*, like *RSLExpresion*, is a generic interface and contains a method *test*. The translation of the three forms of list creation is defined below.

RSL:

$\langle$value_expr$_1$, ..., value_expr$_n\rangle$
$\langle$value_expr$_i$ .. value_expr$_j\rangle$
$\langle$value_expr$_e$ | binding **in** value_expr$_l$ • value_expr$_c\rangle$

Java:

```
new RSLListDefault<T1>(new T1[]{V1 , ... , Vn})
new RSLListDefault<Integer>(Vi , Vj)
Vl.listComp(
  new RSLExpression<Te>() {public Te action(Te b) {return (Ve);}},
  new Testable<Te>(){public boolean test(Te b) {return (Vc);}}
)
```

T_1 is the translation of the type of the elements determined from the type of the first element value_expr$_1$.
V_1 to V_n are the translations of the value expressions value_expr$_1$ to value_expr$_n$.
V_i and V_j are the translations of the value expressions value_expr$_i$ and value_expr$_j$.
V_l is the translation of value_expr$_l$ which must evaluate to a list.
T_e is the translation of the type of value_expr$_e$.
b is the translation of the binding
V_e is the translation of value_expr$_e$ and V_c is the translation of value_expr$_c$.

Examples of all three kinds of list creation and their translation in Java are shown in Example 2.17.

In RSL, a number of operators on lists have been defined. These operators are implemented as methods in the *RSLList* interface. As an example

Example 2.17 List creation – examples.

⟨**true**, **false**, **true**, **false**⟩,
⟨1..10⟩
⟨2∗n | n **in** ⟨0,1,2,3⟩ • n \ 2 = 0⟩

```
new RSLListDefault<Boolean>(new Boolean[]{true, false, true,
    false});
new RSLListDefault(1, 10);
(new RSLListDefault<Integer>(new Integer[]{0,1,2,3})).
    listComp(
       new RSLExpression<Integer>(){
                public Integer action(Integer n) {return new
                    Integer(2*n); }},
            new Testable<Integer>(){
                public boolean test(Integer n) { return (n
                    % 2 == 0); }}
    );
```

concatenation of lists denoted by ⌢ is translated into the method RSLList< E> concat(RSLList<E>). The translation of the operators are shown in Table 2.7.

Operator	Translation
⌢	RSLList<E> concat(RSLList<E>)
hd	E hd()
tl	RSLList<E> tl()
len	**int** len()
elems	RSLSet elems()
inds	RSLList<Integer> inds()
(i)	<E> get(i)
(i) = j	**void** set(i, j)

Table 2.7: Overview of translation of list operators in RSL to Java.

The use of the operators and translation of their use are shown in Example 2.18.

Set Types

The complex type set in RSL is an unordered collection of distinct values of the same type [11]. The set type in RSL consists of both finite and infinite

Example 2.18 List operators – examples.

$\langle 1,2,3,4,5\rangle \frown \langle 6,7,8,9,10\rangle$

(new RSLList(new Integer[]{1,2,3,4,5})).concat(
   new RSLList(new Integer[]{6,7,8,9,10}));
(new RSLListDefault(new Integer[]{1,2,3,4,5})).get(2);
(new RSLListDefault(new Integer[]{1,2,3,4,5})).hd();
(new RSLListDefault(new Integer[]{1,2,3,4,5})).tl();
(new RSLListDefault(new Integer[]{1,2,3,4,5})).len();
(new RSLListDefault(new Integer[]{2,2,2,4,4,4)).elems();
(new RSLListDefault(new Integer[]{2,2,2,4,4,4)).inds();
(new RSLListDefault(new Integer[]{5,4,3,2,1})).get(1);
il.set(i, 7);
```

sets. Only finite sets are considered here. In Java, there exists an interface *Set*, which defines the concept of a set in Java. An instance of a class implementing the *Set* interface holds the same properties as a set in RSL. As for the translation of lists in RSL an interface, *RSLSet*, defining methods corresponding to the operators in RSL has been defined. An implementing class, *RSLSetDefault*, based on a variable of a class implementing the *Set* interface has also been defined.

The translation from RSL into Java is as follows:
RSL:
t-**set**
Java:
RSLSetDefault<T>, where T is the translation of t.

In RSL, sets may be created in three ways; by enumerating the elements, as an interval of integers, or by a comprehended set expression. Comprehended set expressions are not supported, because they can result in infinite sets. However, if the comprehended set expression is on a special form it is possible to define a translation:

{F(x)|x:t• x ∈ S ∧ P(x)}

S must be a finite set and both the predicate P and the expression F must be possible to translate using the same idea as for lists.

The enumerated and ranged set expressions are translated like the enumerated list expressions and ranged list expressions. The translation from RSL into Java of these two kinds of set expressions are defined below:

RSL:

{value_expr$_1$, ..., value_expr$_n$}
{value_expr$_i$ .. value_expr$_j$}

Java:

```
new RSLSetDefault<T1>(new T1[]{V1,...,Vn })
new RSLSetDefault<Integer>(Vi, Vj)
```

T_1 is the translation of the type of the elements determined from the first element.
V_1 to V_n is the translation of the value expressions value_expr$_1$ to value_expr$_n$.
V_i and V_j is the translation of the two value expressions value_expr$_i$ and

value_expr$_j$.

Examples of the two ways of creating set are shown in Example 2.19.

Example 2.19 Set creation - examples.

{1,2,3,4}
{1..4}

```
new RSLSetDefault<Integer>(new Integer[]{1,2,3,4});
new RSLSetDefault<Integer>(1,5);
```

In RSL, a number of operators on sets have been defined. The translation of these operators are defined as methods in the *RSLSet* interface and implemented in the *RSLSetDefault* class. The translation of the operators are shown in Table 2.8

Operator	Translation
$\in$	**boolean** isIn()
$\ni$	**boolean** isNotIn()
$\cup$	RSLSet<E> union(RSLSet<E>)
$\cap$	RSLSet<E> intersect(RSLSet<E>
$\setminus$	RSLSet<E> difference(RSLSet<E>)
$\subseteq$	**boolean** subSet(RSLSet<E>)
$\subset$	**boolean** properSubSet(RSLSet<E>)
$\supseteq$	**boolean** superSet(RSLSet>E>)
$\supset$	**boolean** properSuperSet(RSLSet<E>)
card	**int** card()

Table 2.8: Overview of translation of set operators in RSL to Java.

The use of the operators are shown in Example 2.20 as well as their translation in Java.

Map Types

The complex type map in RSL is a table–like structure, which maps values of one type into values of possibly another type [11]. Maps may be infinitely large. Like for lists and sets, only finite versions of maps are considered in this project. In Java, there is an interface named *Map*, which serves the

Example 2.20 Use of infix operators on sets.

$1 \in \{1,2,3,4,5\}$
$7 \notin \{1,2,3,4,5\}$
$\{1,2\} \cup \{3,4\}$
$\{1,2\} \cap \{2,3\}$
$\{1,2,3,4,5\} \setminus \{4,5\}$
$\{1,2,3\} \subset \{1,2,3\}$
$\{1,2,3\} \subseteq \{1,2,3\}$
$\{1,2,3\} \supset \{1,2,3\}$
$\{1,2,3\} \supseteq \{1,2,3\}$
card $\{1,2,3,4\}$

```
(new RSLSetDefault<Integer>(new Integer[]{1,5})).isin(1);
(new RSLSetDefault<Integer>(new Integer[]{1,5})).isNotin(7);
(new RSLSetDefault<Integer>(new Integer[]{1,2})).union(
     new RSLSetDefault<Integer>(new Integer[]{3,4}));
(new RSLSetDefault<Integer>(new Integer[]{1,2})).intersect(
     new RSLSetDefault<Integer>(new Integer[]{2,3}));
(new RSLSetDefault<Integer>(new Integer[]{1,2,3,4,5})).
   difference(
     new RSLSetDefault<Integer>(new Integer[]{4,5}));
(new RSLSetDefault<Integer>(new Integer[]{1,2,3})).subSet(
     new RSLSetDefault<Integer>(new Integer[]{1,2,3}));
(new RSLSetDefault<Integer>(new Integer[]{1,2,3})).properSubSet(
     new RSLSetDefault<Integer>(new Integer[]{1,2,3}));
(new RSLSetDefault<Integer>(new Integer[]{1,2,3})).superSet(
     new RSLSetDefault<Integer>(new Integer[]{1,2,3}));
(new RSLSetDefault<Integer>(new Integer[]{1,2,3})).
   properSuperSet(
     new RSLSetDefault<Integer>(new Integer[]{1,2,3}));
(new RSLSetDefault<Integer>(new Integer[]{1,2,3,4,5})).card()
```

same purpose namely to provide a mapping of keys into values. In RSL, it is possible to have a non-deterministic map, i.e., a map where a value of the domain is mapped to several values in the range of the map. Since non-determinism is seldom wanted in an implemented system, non–deterministic maps are not considered here.

The implementation of maps in the translation are very similar to the implementation of lists and sets. An interface and an implementing class have been developed. The interface is named *RSLMap* and the implementing class *RSLMapDefault*. The methods defined in the interface correspond closely to the operators defined on maps in RSL.

The translation from RSL into Java is as follows:
RSL: $t_1 \ \overrightarrow{m} \ t_2$
Java: RSLMapDefault<T_1 , T_2>, where T_1 is the translation of t_1 and T_2 is the translation of t_2.

In RSL, there are two ways to create a map; either by enumerating the elements as pairs or by creating a comprehended map expression. The comprehended map expression consist of two value expressions, one value expression expressing the domain of the map, and one value expression expressing the range of the map. The comprehended map expression may result in both non–deterministic and infinite maps, and they are therefore disallowed. However, if the comprehended map expression is on a special form it may be translated anyway:

$[\, x \mapsto F(x) | x{:}t \bullet x \in S \wedge P(x) \,]$

S must be a finite set and F(x) and P(x) must be possible to translate as previously done with lists and sets.

The only allowed form of creating maps are by using an enumerated map expression. The definition of the translation from RSL into Java is shown below.

RSL:

$[\, \text{value\_expr}_{d1} \mapsto \text{value\_expr}_{r1}, \ldots, \text{value\_expr}_{dn} \mapsto \text{value\_expr}_{rn} \,]$

Java:

```
new RSLMapDefault<T1 , T2>(
  new T1 [ ] { Vd1 , ... , Vdn } ,
  new T2 [ ] { Vr1 , ... , Vrn }
)
```

T_1 is the translation of the type of value_expr$_{d1}$
T_2 is the translation of the type value_expr$_{r1}$.
V_{ai} is the translation of the corresponding value_expr$_{ai}$.

Examples of the creation of maps are shown in Example 2.21. There are three constructors to allow for different ways of creating maps. The first constructor takes no arguments and creates an empty map. The second constructor takes two objects as argument and creates a map with one entry. The third constructors takes two arrays as arguments and it creates a map where the elements of the first array is mapped into the elements of the second array.

Example 2.21 Creation of maps.

[ ]
[1 ↦ ″one″]
[2 ↦ ″two″, 3 ↦ ″three″]

```
RSLMapDefault<Integer, String>();
RSLMapDefault<Integer, String>(1, "one");
RSLMapDefault<Integer, String>(new Integer[]{2,3}, new String[]{
    "two", "three"});
```

There are a number of operators in RSL for manipulating maps. These operators consist of both prefix and infix operators, all of which are translated as dynamic methods in Java. The prefix operators are translated as methods taking no arguments, while the infix operators are translated as methods taking one argument. Even though the methods are dynamic and therefore must be invoked on an object they do not change the object, on which they are invoked, instead they return a new object. An example of this is an invocation of the method override on one map with another map as argument, which neither changes the map on which override is invoked, nor the map given as arguments. overwrite returns a new map created from the content of the map on which it is invoked and the map provided as argument. The translation of the operators are defined in Table 2.9.

Operator	Translation
$\cup$	RSLMap<K,V> union(RSLMap<K,V>)
$\dagger$	RSLMap<K,V> override(RSLMap<K,V>)
$\backslash$	RSLMap<K,V> restrictBy(RSLSet<K>)
/	RSLMap<K,V> restrictTo(RSLSet<K>)
$\circ$	RSLMap compose(RSLMap)[a]
dom	RSLSet<K> dom()
rng	RSLSet<V> rng()

[a] The missing generic types is due to the involvement of three types: the key of the inner map, the value of the inner map which is the same as the key of the outer map, and the value of the outer map. Use of more generic types in a method than defined in the class signature is not permitted in Java 1.5.

Table 2.9: Overview of translation of RSL map operators into Java.

The use of the operators and their translations are shown in Example 2.22

2.3.3 Type Definitions

There are a number of type definitions in RSL, which are used to create new types. The type definitions in RSL are:

1. Sort definitions
2. Variant definitions
3. Short record definitions
4. Union definitions
5. Abbreviation definitions

The purpose of type definitions is to create new types, which may be used elsewhere in a specification. The variant definition, e.g. creates a type with several alternatives, which a value of the type may take. In Java, there is only one way to create new types, and that is by creating a new class. Therefore, the translations of type definitions all involve generation of one or more classes in Java.

In RSL, there is structural equivalence between types but not name equivalence. Therefore, the specification in Example 2.23 is valid, even though a variable of one abbreviation type is a assigned to a variable of another abbreviation type. The two abbreviation definitions are abbreviations for the same type, and the assignment is therefore allowed. In Java, on the other hand, there is name equivalence between types. Name equivalence means that two

Example 2.22 Use of map operators.

[1↦1.0,2↦2.0] ∪ [3↦3.0, 4↦4.0]
[1↦1.0,2↦2.0] † [1↦3.0]
[1↦1.0,2↦2.0] \ {2}
[1↦1.0,2↦2.0] / {1}
[1↦1.0,2↦2.0] ° [1.0↦``one'']
dom [1↦1.0,2↦2.0]
rng [1↦1.0,2↦2.0]

```
new RSLMapDefault<Integer , Double>(new Integer[]{1,2},
                                    new Double[]{1.0,2.0}).union(
    new RSLMapDefault<Integer , Double>(new Integer[]{3,4},
                                        new Double[]{3.0,4.0});
new RSLMapDefault<Integer , Double>(new Integer[]{1,2},
                                    new Double[]{1.0,2.0}).
                                        override(
    new RSLMapDefault<Integer , Double>(new Integer[]{1},
                                        new Double[]{3.0});
new RSLMapDefault<Integer , Double>(new Integer[]{1,2},
                                    new Double[]{1.0,2.0}).
restrictionBy(new RSLSetDefault<Integer>(2);
new RSLMapDefault<Integer , Double>(new Integer[]{1,2},
                                    new Double[]{1.0,2.0}).
restrictionTo(new RSLSetDefault<Integer>(1);
new RSLMapDefault<Integer , Double>(new Integer[]{1,2},
                                    new Double[]{1.0,2.0}).
                                        compose(
    new RSLMapDefault<Double , String>(1.0,"one");
new RSLMapDefault<Integer , Double>(new Integer[]{1,2},
                                    new Double[]{1.0,2.0}).dom();
new RSLMapDefault<Integer , Double>(new Integer[]{1,2},
                                    new Double[]{1.0,2.0}).rng();
```

types are considered to be equivalent if the names of the types are the same. In Java, it is possible to create new types containing the same components, and then name them differently. However, it is not possible to assign a value of one of these types to a variable of another type. The two types in Java are different types, whereas in RSL, the two types are the same. There are two possible strategies for solving this.

Example 2.23 Structural equivalence in RSL

```
scheme PRODUCT_TEST =
class
  type
    Product_1 = Int × Real,
    Product_2 = Int × Real
  variable
    p_1 : Product_1 := (1, 1.0),
    p_2 : Product_2 := (2, 2.0)
  value
    test : Unit → read p_1 write p_2 Unit
    test() ≡
      p_2 := p_1
end
```

The first strategy is to invent a naming convention and use this for all abbreviation types defined in RSL, thereby ensuring that all equivalent abbreviations are translated as one type in Java.

The second strategy is to let both abbreviation types be created with the names given, and then ensure by other means that it is possible to assign a variable of one type to a variable of another type. One way to ensure this is to create a common super type and then let variables which are defined be of the super type, rather than one of the specific types.

Both strategies have the drawback, that the translation is quite different from the specification. The first solution is chosen since it provides the code with the least number of classes. The tool carrying out the translation should create a class named with an underscore and the content of the type expression seperated by underscore. The Product_1 type abbreviation in Example 2.23 should result in a Java class: `_Int_Real`.

Sort Definition

A sort definition specifies a type which has yet to be defined. The sort type can be used in type expressions, e.g. in other type definitions. The translation of the sort type should have the same properties. The translation of the sort definition is an empty class, because this resembles the same properties.

The translation from RSL into Java is as follows:
RSL:

type t

Java:

```
public class T {}
```

Where T is the translation of the name t.

Variant Definitions

A variant definition is a convenient way to group a number of values and functions on sort definitions [11]. A variant definition is a grouping of alternatives, which may either be constants or record constructors with components defining the content of the alternative. The types may be recursively defined.

In the translation into Java, the same properties are desired. There is a need for a type which is a grouping of alternatives. There is only one concept in Java which allows for values of different types to be assigned to the same variable, and that is if the types in Java are subtypes of a general type, and that the variable is of the general type.

A variant definition is translated as an abstract class with one extending class for each alternative.

The translation from RSL into Java is as follows:
RSL:

type t_1 == a_1 | ... | a_n

Java:

```
public abstract class T1 {
  public abstract boolean equals(Object o);
  public abstract String toString();
}
```

public class A_1 **extends** T_1 {...}

public class A_n **extends** T_1 {...}

T_1 is the translation of the name t_1.
A_1 is the translation of the name a_1.
A_n is the translation of the name a_n.

Translation of a constant alternative:
RSL:

type t == a

Java:

```
public class A extends T
  public boolean equals(Object o) {
    if(o instanceof A)
      return true;
    else
      return false;
  }

  public String toString() {
    return "A";
  }
}
```

T is the translation of the name t.
A is the translation of the name a.

The reason for the special implementation of the equals method in the class A, is that whenever an A object is created, it should be identical to other objects of the type. This could also be achieved by implementing the singleton design pattern [7]. This solution, however, would lead to two different ways of creating objects, because objects are created by methods and not constructors in the singleton design pattern.
Translation of a record constructor alternative:
RSL:

type t = a(t_2)

Java:

```
public class A extends T {
  public T2 _v1;
```

```
  public A (T2 _v1) {
    this._v1 = _v1;
  }

  public boolean equals(Object o) {
    if(o instanceof A) {
      if(!_v1.equals(((T2) o)._v1) {
        return false;
      }
      return true;
    }
    return false;
  }

  public String toString() {
    return "A(" + _v1 + ")";
  }
}
```

T is the translation of the name t.
A is the translation of the name a.
T_2 is the translation of type t_2.

A record alternative of a variant definition may specify destructors for each of the components it incoorporates. The purpose of a destructor is to be able to retrieve a component of an alternative. A destructor in RSL corresponds very much to a *get* method in Java, which returns the value of a field in a class. An alternative of a variant type definition may also specify reconstructors. The purpose of a reconstructor is to change a part of a record without changing the rest of the record. In Java, the idea of changing a field in a class would normally be done by a *set* method. However, it should be noted that a reconstructor in RSL is just a convenient way for creating a new value, in which one of the components is changed. The translation cannot be a *set* method in Java but must be a method creating a new object.

The translation of destructors and reconstructors in RSL into Java are as follows:
RSL:

type t_1 == a(get_t : $t_2 \leftrightarrow$ replace_t),

Java:

```
public abstract class T1 { //same as earlier defined }

public class A extends T1 {
```

```
  private T2 _v1;

  public A(T2 _v1) {
    this._v1 = _v1;
  }

  public T2 get_t() {
    return _v1;
  }

  public T1 replace_t() {
    return new A(_v1);
  }

  /*toString and equals method omitted follows same pattern as
      earlier defined.*/
}
```

T_1 is the translation of the name t_1.
A is the translation of the name a_1.
T_2 is the translation of the type t_2.

In Example 2.24, a variant definition with two alternatives a constant and a recursively defined record constructor is shown.

If the variant definition consists of only constants, it is tempting just to use an enumeration, as shown in Example 2.25. This would also be more effecient than creating an object for each value of the variant. However, in order to make the translation consistent, the same method is chosen for all kinds of variant definitions.

Example 2.26 shows a variant definitioncontaining destructors, reconstructors, and the translation of these.

The simple wildcard, which does not contain any components, is just ignored, because it is impossible to limit the number of classes extending a general super class in Java. Either a class allows for extension, which is needed because the other alternatives already extend the abstract class or a class can be declared *final* and thereby disallow any extensions. The wildcard constructor, which contains one or more components, is also just ignored.

Variant definitions are not just used for recursive definitions. They can also be used to form a union of types which are otherwise unrelated, as shown in Example 2.27

Example 2.24 Recursive variant type definition

type
Collection == empty | add(Elem, Collection),
Elem

```
public abstract class Collection {
/*equals and toString methods omitted*/
}

public class empty extends Collection {
    public boolean equals(Object o) {
        if(o instanceof empty)
            return true;
        else
            return false;
    };

    public String toString() {
        return "empty";
    }
}

public class add extends Collection {
    private Elem _v1;
    private Collection _v2;

    public add(Elem _v1, Collection _v2) {
        this._v1 = _v1;
        this._v2 = _v2;
    }

    public boolean equals(Object o) {
        if(o instanceof empty) {
            if(!(this._v1.equals(((add) o)._v1))) {
                return false;
            }
            if(!(this._v2.equals(((add) o)._v1))) {
                return false;
            }
            return true;
        }
        return false;
    }
    /*toString method omitted*/
}

/*Translation of Elem omitted*/
```

Example 2.25 Translation of variant type definition using an enumeration.

type
Color == black | white

```
public enum Color{black, white};
```

Example 2.26 Variant type definition having constructors, destructors and reconstructors

type
List == empty | add(head : Elem ↔ replace_head, tail : List)

```
public abstract class List {
    /*equals and toString method omitted*/
}

public class empty extends List {
    /*equals and toString method omitted*/
}

public class add extends List {
    private Elem _v1;
    private List _v2;

    public add(Elem head, List tail) {
        _v1 = head;
        _v2 = tail;
    }

    public Elem head() {
        return _v1;
    }

    public List tail() {
        return _v2;
    }

    public List replace_head(Elem e) {
        return new add(e, _v2);
    }

    /*equals and toString method omitted*/
}
```

Example 2.27 Not recursive variant definition.

type
  Figure ==
    box(length : **Real**, width : **Real**) |
    circle(radius : **Real**) |
    triangle(base_line : **Real**, left_angle : **Real**, right_angle : **Real**)

```
public abstract class Figure {
    /*equals and toString method omitted*/
}

public class box extends Figure {
    private double _v1;
    private double _v2;

    public box(double length, double width) {
        _v1 = length;
        _v2 = width;
    }
    public double length() {
        return v1;
    }
    public double width() {
        return v2;
    }

    /*equals and toString method omitted*/
}

public class circle extends Figure {
    private double _v1;

    public circle(double radius) {
        _v1 = radius;
    }
    public double radius() {
        return _v1;
    }

    /*equals and toString method omitted*/
}
```

⋮

Short Record Type Definitions

Short record definitions are short hand for variant definitions with only one alternative. Thus, the translation of a short record definition is very similar to the one for a variant definition. The destructor and reconstructor of a short record definition are optional like for a variant definition. Since the short record definition has only one alternative, there is no need for an abstract class and a class inherited from this.

The translation from RSL into Java is as follows:
RSL:

type t :: get_c_1 : t_1 get_c_2 : t_2 $\leftrightarrow$ replace_c_2,

Java:

```
public class T {
  private T1 _v1;
  private T2 _v2:

  public T(T1 _v1, T2 _v2) {
    this._v1 = _v1;
    this._v2 = _v2;
  }

  public T1 get_c1() {
    return _v1;
  }

  public T2 get_c2() {
    return _v2;
  }

  public T replace_c2(T2 _c2) {
    return new T(_v1, _c2);
  }
}

//Translation of t1 and t2 omitted
```

T is the translation of the name t.
T_1 is the translation of the type t_1.
T_2 is the translation of the type t_2.

An example of translation of a short record definition is shown in Example 2.28.

Example 2.28 Translation of a short record definition.

```
scheme SHORT_RECORD =
class
  type
    MySRD :: sel_Real : Real sel_Int : Int
end
```

```
public class MySRD{
    private double _v1;
    private int _v2;

    public MySRD(double _v1, int _v2) {
        this._v1 = _v1;
        this._v2 = _v2;
    }

    public double sel_Real() {
        return _v1;
    }

    public int sel_Int() {
        return _v2;
    }

    /*equals and toString method omitted*/
}
```

Union Type Definition

Union definitions are short hand for variant definitions. They have been excluded from the translation, because they allow omitting constructors of the underlying variant type. This makes it difficult to determine which alternative to use at a given point, because it is not explicitly stated. The union definitions are only short hands for variant definitions, therefore the removal of union definitions does not remove any power of RSL. It does, however, make writing specifications a little more tedious.

Abbreviation Type Definition

An abbreviation definition consists of an identifier and a type expression describing the type. The identifier can be used as a reference to the type expression. The abbreviation type gives a kind of encapsulation of the details concerning the type. The idea of a class in Java is to be an encapsulation of details, this is the reason that a class in Java is chosen as translation for an abbreviation definition.

Example 2.29 Abbreviation definition

type
newType = t1 × t2,
t1,
t2

```
public class newType{
  public t1 _v1;
  public t2 _v2;
 /*equals and toString method omitted*/
}

public class t1 {
/*equals and toString method omitted*/
}
public class t2 {
/*equals and toString method omitted*/
}
```

2.3.4 Subtypes

In RSL a type is a subtype of another type, if the former is a subset of the latter. The rules for type checking in RSL dictate that the type checking

should only consider the maximal types according to a set of rules for determining maximal types. Therefore, the specification in Example 2.30 does not violate the rules for type checking in RSL. The concept of applying a method with an argument which is of a wider type than allowed cannot be done in Java. This is the reason, that subtypes are not translated in this project.

Example 2.30 Specification applying a maximal type to a function of a subtype.

```
scheme SUBTYPE =
class
   value
      function_a : Nat → Bool
      function_a(a) ≡ true,
      function_b : Nat → Bool
      function_b(b) ≡ function_a(0−b)
end
```

However, one could imagine a solution for subtypes using the assertion feature in Java. The solution would involve inserting an assertion statement before and after each use of a statement or an expression involving a field of a subtype, a method taking a subtype as argument, or a method returning a subtype. The assertion statement should use a translation of the subtype predicate specified as assertion expression. In Example 2.31, an example of translation of the use of **Nat** is shown.

2.4 Values in RSL

The following section is concerned with the values in RSL, how to define values using value definitions, and how to express them using value expressions. First the value definitions are described and afterwards the value expressions are described along with their translation in Java and possible alternatives are considered.

2.4.1 Ordering of Variables and Values

There is a challenge, when translating explicit value definitions and variable declarations in RSL, which are translated as fields in a class in Java. Both

Example 2.31 Translation of a subtype using assertions.

variable
  val : **Nat** := 1
test_case
  [t1] val := 2,
  [t2] val

For an explanation of **test_case** see Section 2.8.

```
public static int val = 1;

public static void main(String[] args) {
    assert (val > 0);
    System.out.println("[t1]: ");
    val = 2;
    assert (val > 0);
    System.out.println("[t2]: " + val);
}
```

in RSL and in Java it is possible to define these values or fields in terms of each other, see Example 2.32.

Example 2.32 Ordering problem for values and variables.

variable
  i : **Real** := r
value
  r : **Real** = s + 1,
  s : **Real** = 5.4

```
public class Ordering_1 {
    public double i = r;
    public static final double r = s + 1;
    public static final double s = 5.4;
}
```

In Java, the order of fields in a class does not matter, except when they are initialized at the time of creation. The Java source code presented in Example 2.32 is not valid, because the initialization of the first field is depending on the second field, and the value of the second field is not known at the time of creation of the first. The variables may be initialized using the statements shown in Example 2.32 but they need to be ordered in another way to be valid. The correct ordering is shown in Example 2.33.

Example 2.33 Correct ordering for the field in Java.

```
public class Ordering_2 {
    public final double s = 5.4;
    public final double r = s + 1;
    public double i = r;
}
```

2.4.2 Value Definitions

The idea of a value definition is to define a value and give it a name by which it may be referenced elsewhere in a specification.

In RSL, it is possible to overload these values, i.e., to use a name more than once for different values. Java also has the possibility of overloading, but only methods may be overloaded. The overloaded versions of a method in Java must have different parameters. A different return type is not enough. It is therefore not possible to reuse all names in RSL directly in Java.

Possible solutions to this problem include:

1. Disallow overloading in specifications to be translated.

2. Allow overloading in RSL which corresponds to the overloading allowed in Java.

3. Allow overloading in RSL, and use a naming convention in the translation into Java.

The second suggestion has been chosen, because it allows for some kind of overloading, but it does not present a problem in the implementation. The third solution could also have been chosen, but it would require the translator to keep track of identifiers and their types, and then, based on the type of the context, insert the correctly renamed identifier in Java.

Explicit Function Definitions

An explicit function definition in RSL is a function which is specified using a value expression for determining the outcome of using the function. It is explicitly specified how the to get the result from the function parameters and values in the specification. For an explicit function definition to be translated, it must only use value expressions for which translation are defined.

An explicit function definition in an RSL specification corresponds to a method definition in Java. They both take values as parameters and may

return some kind of value.

An explicit function definition has the form:

single_typing formal_function_application ≡ value_expression [pre_condition]

The single typing must be a binding using an id or an op identifier and a type expression. The maximal type of the type expression must be a function type [11]. If the identifier is an id the formal function application of the explicit function definition must be an id application.

In this work, only functions using id applications are considered because prefix and infix applications are intended for overloading and redefining the built–in operators, which Java does not allow. A translation of prefix and infix applications could be to create the methods corresponding to the function and let expressions using the redefined prefix or infix expressions be translated as method invocations of methods created.

For an id application it must hold that there are the same number of identifiers in the formal function parameter list as there are type expressions in the first part of the function type expression. This simply means that there must be an identifier for each of the types in the argument of the signature of the explicit function definition.

These limitations on the functions in RSL ensures that functions have the form which is shown in the translation.
RSL:

id : type_expr$_1$ × ... × type_expr_n → type_expr$_{n+1}$
id(binding$_1$,...,binding$_n$) ≡ value_expr

Java:

public [**static**] T_{n+1} id (T_1 b_1 , ... , T_n b_n) V

T_i is the translation of type_expr$_i$.
V is the translation of value_expr.
b_1 to b_n are the translation of binding$_1$ to binding$_n$. Whether or not the keyword **static** is added depends on the context, a discussion of this can be found in Section 2.2.6.

The translation of value expressions are dealt with in Section 2.4.3.

As shown in the Example 2.34, a number of variables are created in the translation, which we can clearly see are not necessary. The closest translation is shown in Example 2.35.

Example 2.34 Listsum translation.

listSum : **Int*** → **Int**
listSum(il) ≡
  if il = ⟨⟩ **then**
    0
  else
    hd il + listSum(**tl** il)
  end

```
public static int listsum(RSLList<Integer> il) {
    int _v0 = 0;
    if(il.equals(new RSLListDefault())) {
        int _v1 = 0;
        _v1 = 0;
        _v0 = _v1
            }
    else {
        int _v1 = 0;
        _v1 = il.hd() + listSum(il.tl());
        _v0 = _v1
            }
    return _v0;
}
```

Example 2.35 Listsum translation closest to specification

```
public static int listsum(RSLList<Integer> il) {
    if(il.equals(new RSLListDefault())) {
        return 0;
    }
    else {
        return il.hd() + listSum(il.tl());
    }
}
```

The reason for using the first translation is that for nested constructs using blocks, there is not always a return statement in each branch, which is required in Java. Therefore, a variable declaration statement is inserted in the top of a block in a method and this statement is returned at the end of the block. Constructs creating new blocks like the if–else statement inserts a new variable in the top of the blocks created and an assignment statement a the end of the blocks. The assignment statement assigns the local variable in the block to the variable of the outer block.

Implicit Function Definitions

Implicit function definitions are as the name suggest, implicit, and therefore not considered in this project. There may, however, be a number of special cases in which an implicit function definition can be translate, but these are also not considered here.

Explicit Value Definitions

In RSL, an explicit value definition defines and gives name to a constant value in RSL, i.e. a value, which cannot be changed. The value may be referenced in the definitions of other values or functions. An explicit value definition in RSL has the form:

single_typing = value_expr

The way to represent a value in Java, which may be referenced by methods and other values is as a field in a class. To make the value unchangeable the keyword **final** is added. This project does not consider product type expression in other places than as part of a function type expression.

Therefore the definition has the form shown in the translation.
RSL:

id : type_expr = value_expr

Java:

```
public [static] final T Id = v;
```

T is the translation of type_expr.
V is the translation of value_expr
Id is determined from the identifier id in RSL.
Whether or not the keyword **static** is added depends on the context, a discussion of this can be found in Section 2.2.6.

An example of the translation of explicit value definitions is shown in Example 2.36.

Example 2.36 Translation of explicit value definitions.

value
constant_one : **Int** = 1,
constant_two : **Text** = ″a″

```
public static final int constant_one = 1;
public static final String constant_two = "a";
```

Implicit Value Definitions

Implicit value definitions are like implicit function definitions, not considered in this project. Like for implicit function definitions, there may be a number of special cases where the implicit definition carries enough information to be translated.

2.4.3 Value Expressions

In RSL, there is only one way to describe a value and that is by a value expression. In Java there are three levels of constructs for describing values:

1. Blocks.
2. Statements.
3. Expressions.

The problem with different number of levels becomes evident when dealing with a value expression in RSL containing other value expressions. As an example, an if–then–else expression in RSL contains a value expression as condition. The condition determines whether to select the first or the second branch of the if–then–expression. The translation of an if–then–else expression in RSL is, as stated later, an if statement in Java. The if statement in Java must have an expression as condition. When a specification in RSL uses an if–then–else expression as condition of another if–then–else expression, then the outer if–then–else expression is translated as an if statement in Java. The condition cannot be translated as another if statement, because the condition of the outer if statement in Java must be an expression and not a statement. This is shown in Example 2.37.

Example 2.37 Not allowed translation of nested **if–then–else** expression.

if if a = b **then false else true end then**
c
else
d
end

```
if(if(a == b) return false; else return true;)
    return c;
else
    return d;
```

One possible solution of the problem shown in Example 2.37 could be to rewrite the condition using the conditional expression in Java `a == b ? false : true`. This does solve the problem in the general case, because other type of statements does not have an expression counterpart. A more general solution could be to translate the condition as an auxiliary method returning a boolean value, and let the translation of the condition of the outer if statement be a method invocation of the auxiliary method created. The idea is shown in Example 2.38.

Example 2.38 Allowed translation of nested **if–then–else** expression.

if if a = b **then false else true end then**
c
else
d
end

```
if(_condition1())
    return c;
else
    return d;

private boolean _condition1() {
    if(a == b)
        return false;
    else
        return true;
}
```

The general strategy for dealing with the fact that Java has three levels for expressing values, while RSL only has one, is to allow any value expression in RSL to be translated to either of the levels in Java.

A *block* in Java is a possibly empty collection of statements. There exists a special statement in Java, namely the expression statement, which turns an expression into a statement.

If a block is needed in the translation and the direct translation of the RSL value expression is a Java expression, then the Java expression can be wrapped in an expression statement, and the expression statement can be wrapped in a block. The problem is more complicated if a RSL value expression is translated into a Java statement, and the nesting construct in Java only allows for a Java expression. In order to solve this, the statement, which is the translation of the RSL value expression is, placed in an auxiliary method, and a method invocation of the auxiliary method is inserted instead. A method invocation is an expression in Java. One could imagine three methods, which all take a RSL value expression as parameter and return one of the Java constructs:

- `make_block(RSLValueExpression e)`
- `make_statement(RSLValueExpression e)`
- `make_expression(RSLValueExpression e)`

The function `make_block` either translates the *RSLValueExpression* or calls `make_statement` and wraps the result into a block. The function `make_statement` either translates the *RSLValueExpression* or calls `make_expression` and wraps the result in an expression statement. If `make_expression` is called with a *RSLValueExpression*, which is translated as a statement in Java, it inserts a method invocation and creates an auxiliary method containing the translation of the *RSLValueExpression*. If `make_expression` is called with an RSL expression which is translated as an expression it just returns an expression.

The following sections deals with the translation of different value expressions in RSL.

If–then–else Expressions

An if–then–else expression in RSL correspond very much to an if statement in Java. They both contain an expression, which must evaluate to a boolean value determining whether to select the first or second alternative. In RSL it is possible to list a more than two alternatives by using the **elsif** keyword and specifying the condition for the alternative. An if–then–else expression

using **elsif** construct can be rewritten using only **if then else**, see Example 2.39 [11]. An if statement in Java is chosen as translation of an if–then–else expression in RSL.

Example 2.39 Rewrite elsif construct.

```
if a = b then
   0
elsif a = c then
   1
   elsif a = d then
   2
else
   3
end
```

Is equivalent to

```
if a = b then 0 else
   if a = c then 1 else
      if a = d then 2 else
         3
      end
   end
end
```

```
if(a == b)
    return 0;
else if(a == c)
    return 1;
else if(a == d)
    return 2;
else
    return 3;
```

Case Expressions

Case expressions in RSL allow for a choice between several alternatives [11]. A case expression consists of a value expression and a list of case branches. A case branch consists of a pattern and a value expression. By evaluating the value expression of the case expression and matching it with the patterns in the case branch list, a branch may be selected, and the corresponding value

expression is evaluated. This description seems very similar to the switch statement Java, which also consists of an expression, that is compared with the value of the cases. If one of the values is matched the corresponding block of the case is evaluated. Here the similarities between the switch statement in Java and the case expression in RSL stop, because the switch statement in Java can only have patterns of simple types, i.e., **char**, **int** or **double**. The case expression of RSL can have literal patterns, name patterns, record patterns, list patterns, product patterns, and wildcard patterns allowing for a large variety of tests. Therefore, the translation of the case expression in RSL cannot be a switch statement in Java, but is instead a set of if statements in Java using different conditions depending on the pattern of the case expression.

Only name patterns, literal patterns, and record patterns of variant definitions are considered here. The translation of the patterns will be covered in the following. Example 2.40 shows the translation of a case expression using only name patterns. The names must be names of variant constants and due to the translation of variant constants as classes, the match is done using an **instanceof** expression in Java.

In Example 2.41 the translation of a case expression in RSL using both name patterns and a simple record pattern is shown. The name pattern is treated in the same way as shown in Example 2.40. The record pattern is treated a little different. The condition of the if–statement in the translation of a record pattern is the same as for the name pattern. In case of a match the first part of the if–block in Java is to define some local variables according to the names specified in the record pattern. The variables are set to the values of the variant by calling the destructors of the variant.

Example 2.42 shows the translation of a case expression in RSL using value literals and a wildcard pattern. The condition for the value literal pattern uses an infix expression with the Java equivalence operator == or a method invocation of the equals method. A wildcard pattern is translated as an else–block of the last if–statement.

Value Literals

Value literals in RSL are translated by creating a corresponding value literal in Java, according to the translation of the built–in types specified in Section 2.3. As an example a value literal of type real in RSL is translated into a value literal of type double in Java. This simple way of just creating a corresponding value literal could create problems with sizes of types according to the discussion in Section 2.3. One solution could be to add a kind of validation of a value literal in RSL before creating a corresponding value literal

Example 2.40 Translation of a case expression using name patterns.

```
scheme CASETEST_1 =
class
   type
      Colour == Black | White
   value
      invert: Colour → Colour
      invert(c) ≡
         case c of
            Black → White,
            White → Black
         end
end
```

```
/* Translation of Colour is omitted, but should
   be translated as stated for short record
   type definitions.
*/
public class CASETEST_1 {
    public static Colour invert(Colour c) {
        Colour _v0 = null;
        if(c instanceof Black){
            Colour _v1 = null;
            _v1 = new White();
            _v0 = _v1;
        }
        else { if(c instanceof White) {
            Colour _v1 = null;
            _v1 = new Black();
            _v0 = _v1;
        }
        }
        return _v0;
    }
}
```

Example 2.41 Translation of a case expression using record and name patterns.

```
scheme CASETEST_2 =
class
  type
    MyList == Empty | Add(head : Int, tail : MyList)
  value
    addOne: MyList → MyList
    addOne(ml) ≡
      case ml of
        Empty → Empty,
        Add(i, m1) → Add(i + 1, addOne(m1))
      end
end
```

```
/* Translation of MyList omitted in example,
   but is translated as stated for variant
   type definitions.
*/

public class CASETEST_2 {
    public static MyList addOne(MyList ml) {
        MyList _v0 = null;
        if(ml instanceof Empty) {
            MyList _v1 = null;
            _v1 = new Empty();
            _v0 = _v1;
        }
        else {if(ml instanceof Add) {
            MyList _v1 = null;
            int i = ((Add) ml).head();
            MyList m1 = ((Add) ml).tail();
            _v1 = new Add(i + 1, addOne(m1));
            _v0 = _v1;
        }
        }
        return _v0;
    }
}
```

Example 2.42 Translation of a case expression using value literal patterns and a wildcard pattern.

```
scheme CASETEST_3 =
class
  value
    toString: Int → Text
    toString(i) ≡
      case i of
        1 → "One",
        2 → "Two",
        _ → "Unknown"
      end
end
```

```
public class CASETEST_3 {
    public static String toString(int i){
        String _v0 = null;
        if(i == 1) {
            String _v1 = null;
            _v1 = "One";
            _v0 = _v1;
        }
        else {
            if(i == 2) {
                String _v1 = null;
                _v1 = "Two";
                _v0 = _v1;
             }
            else{
                String _v1 = null;
                _v1 = "Unknown";
                _v0 = _v1;
            }
        }
        return _v0;
    }
}
```

in Java, to ensure that the limitations of the type in Java are kept.

Application Expressions

Application expressions in RSL can result in a number of different translations depending on the context of the application expression. The application expression consists of two parts a value expression, which must be the name of a function, a list, a map, a make function of a short record definition, a constructor of a variant or a reconstructor, and a second part which is an optional expression list.

The creation of new records is translated using the constructor defined in the translations of type definitions. The use of destructors and reconstructors is translated as dynamic method invocations according to the translations of them. The application expressions involving list and maps have already been described in Section 2.3.2. Application of a function defined via explicit function definition in RSL is translated as a method invocation of a method in Java.

One could argue that using different translations is not a good solution, and that the constructs should have been translated, so that all application expressions could be treated identically. The drawback of that solution would be that the translated Java source code would not fulfill the requirements for good code practice in Java and not be very object–oriented. Finally the application expression concerning maps and lists would always be different from the application of the functions, so some kind of handling of different translations of application expressions would be needed.

Examples of these application expressions and their translation is shown in Example 2.43.

Bracketed Expressions

In RSL, a bracketed expression is meant for deciding the order in which an expression is evaluated. The same is the case for a parenthesized expression in Java. Parentheses in Java may be used to ensure that the content of the parentheses are evaluated before the context in which the expression appear. The translation of a bracketed expression in RSL is therefore a parenthesized expression in Java.

Basic Expressions

A basic expression in RSL consists of either of the keywords:

- **chaos**

Example 2.43 Translation of record constructors, make function, destructors and reconstructors.

```
type
   MyVariant == Alternative1(getReal : Real ↔ setReal),
   MyShortRecordDefinition :: getInt : Int ↔ Int
value
   listSum : Int* → Int
   listSum(il) ≡
      if il = ⟨⟩ then 0 else hd il + listSum(tl il) end
test_case
   [t1] getReal(Alternative1(5.0)),
   [t2] setReal(5.0, Alternative(4.0)),
   [t3] getInt(mk_MyShortRecordDefinition(1)),
   [t4] setInt(2, mk_MyShortRecordDefinition(1))
   [t5] listSum(⟨1,2⟩)
```

```
/* Translations of MyVariant, MyShortRecordDefinition and listSum
     are omitted*/
public static void main(String[] args) {
     System.out.println("[t1]: " +
          (new Alternative_1(5.0)).getReal());
     System.out.println("[t2]: " +
          (new Alternative_1(4.0)).setReal(5.0));
     System.out.println("[t3]: " +
          (new MyShortRecordDefinition(1)).getInt());
     System.out.println("[t4]: " +
          (new MyShortRecordDefinition(1)).setInt(2));
     System.out.println("[t5]: " + listsum(
        new RSLListDefault<Integer>(new Integer[]{1,2})));
}
```

- **skip**
- **stop**
- **swap**

chaos in RSL represents non–determinism. The concept of non–determinism is not wanted in a program, no translation of this into Java has been defined.
skip is part of the imperative specification style, which is not considered in this project.
stop represents a deadlock in a system which is involved in communication. Communication between parallel systems are not considered in this project, and thus **stop** is not translated.
swap "is a completely under–specified expression — it may terminate or not, may deadlock, may behave non–deterministically" [11, p. 189]. There is no possible translation of **swap** in Java.

Since neither of the basic expressions are considered in this project the use of basic expression is disallowed.

Statement Infix Expressions

Statement infix expressions are not considered here because the operators involved are part of the specifications of parallel systems which are not considered in this project.

Axiom Infix Expressions

In RSL, an axiom infix expression is an expression using an infix connective. Use of the infix connective and their translation are covered in Section 2.3.1.

Value Infix Expression

The translation of a value infix expression in RSL can result in two different kinds of expressions in Java, depending on the operator in RSL. The simple mathematical infix operators considered here, + and *, are both translated as infix expressions in Java using the same simple operators according to the discussion in Section 2.3. The concatenation operator $\frown$ in RSL is translated as a method invocation of the concat method in Java. The left–hand side operand is object of the method invocation, and the right–hand side operand is argument to the method.

The = operator in RSL comparing two values is translated in two different ways depending on whether the type of translation of the operands is a primitive type or a reference type in Java. In cases where the operands of a

value infix expression is translated as primitive types, the translation is an infix expression using the equivalence operator in Java (==). For reference types, the translation is a method call using the equals method of Java. A number infix expression and their translation are shown in Example 2.44

Example 2.44 Translation value infix expressions.

1+2
5∗6+2
⟨1,2,3⟩ ⌢ ⟨4,5,6⟩
1 = 1
"a" = "b"

```
1 + 2
5 * 6 + 2
(new RSLListDefault<Integer>(new Integer[]{1,2,3})).concat(
  new RSLListDefault<Integer>(new Integer[]{4,5,6}))
1 == 1
"a".equals("b")
```

Axiom Prefix Expressions

Axiom prefix expressions concern the prefix connective ˜, and is treated in Section 2.3.1 dealing with type **Bool**.

Universal Prefix Expressions

Universal prefix expressions concern the universal state quantification operator which is a part of the axiomatic specification style which is not considered in this work.

Value Prefix Expressions

Value prefix expressions in RSL are translated as method invocations of a method in Java. The exact translation of each of the operators is treated in the sections on the types of the value expressions involved.

Disambiguation Expressions

Disambiguation expressions are not considered here because they are used to clarify typings in RSL in case of overloading resulting in expressions where the

type cannot be determined. Only simple forms of overloading are considered in this project, and in these cases disambiguation expressions are not needed.

List Expressions

Translation of list expressions are treated in Section 2.3.2.

Set Expressions

Translation of set expressions are treated in Section 2.3.2.

Map Expressions

Translation of map expressions are treated in Section 2.3.2.

2.5 Variable Definitions

Variable definitions are not considered in this project. They are part of the imperative specification style, which is not considered in this project. Suggestion for at translation is given in Chapter 7.

2.6 Axiom Definitions

Axiom definitions are not considered in this project. They primarily deal with the implicit specification style, which is not considered in this project.

2.7 Channel Definitions

Channel definitions are not considered in this project. They belong to a part of RSL, dealing with specifications of parallel systems, which is not considered in this project. Suggestions for a possible translation is given in Chapter 7.

2.8 Test Cases Definitions

Test cases in RSL is an addition invented by the people at UNU/IIST[3]. The basic idea of the test cases is to avoid having to write test code in a programming language, to which RSL is translated by a translator. A test

[3]United Nation University / International Institute of Software Technology

case in RSL consists of an optional identifier and a value expression. When translating a specification containing test case declarations, a main method is created. The test cases are translated as a call to the System.out.println method with an infix expression consisting of the identifier concatenated with the translation of the value expression in a parenthesized expression, as shown in Example 2.45.

Example 2.45 Translation of a test case.

test_case
[t1] ⟨1,2,3⟩

```
public static void main(String[] args) {
    System.out.println("[t1]: " + (
      new RSLListDefault<Integer>(new Integer[]{1,2,3})));
}
```

Chapter 3

Development Strategy

This chapter considers a number of topics in the process of designing and developing a tool for translation from RSL into Java. The tool is referred to as the *translator*. The chapter starts with an overview of some design options, which are used in the discussion of the architectural design and development process of the translator. Afterwards, the architectural design of the translator is presented, followed by an overview of the development process. The last section of the chapter presents the different subsets of RSL used in this work.

3.1 Design Options

The following describes two design methods which will be used in the discussion of the design of the translator in Section 3.2. The section describes the use of a bootstrapping process for developing a translator from scratch, and how to optimize a compiler using bootstrapping. Furthermore, the section presents the visitor design pattern. The descriptions are at a general level, if you are already familiar with these two methods of bootstrapping and the visitor design pattern, this section may be skipped.

3.1.1 Bootstrapping

The concept of bootstrapping originally refers to a story about a man being able to fly by pulling himself up in his bootstraps [6]. The term has been used later on to describe the idea of creating a new tool using the tool itself. The way it is typically done is by creating a simple version of the new tool by hand or other simple tools, and then use the simple version of the tool to create a more advanced version of a tool.

In the development of a language processor, the idea is to develop a language processor for a language using the language itself. First a primitive version of the language processor is created by hand, then this version is used for creating a more advanced version of the language processor.

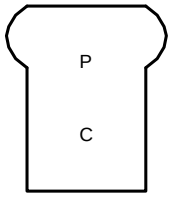
The term has been widened to the concept of processing a language processor using itself. The process may be used for creating a compiler from scratch, for optimizing a compiler, creating a true compiler from a portable compiler, or creating a compiler generating another target language. It is the development of a language processor from scratch and optimizing a language processor, which are of interest in this project and these two processes will be covered in the following.

Tombstone Diagrams

The application of a language processor on either programs or other language processors can be clearly illustrated by tombstone diagrams. The different kinds of diagrams will be briefly introduced in following. A more extensive covering can be found in [19].

An ordinary program is represented by a round-topped tombstone with the name of the program in the head of the tombstone and the implementation language program at the base of the tombstone, an example of a program is shown in Figure 3.1.

Figure 3.1 A program P implemented in C.



A machine, which may execute a program, is represented by a pentagon pointing downwards with the name of the machine code language it is able to execute inside of it, an example of a machine is shown in Figure 3.2.

An interpreter is represented by a rectangular tombstone with the language interpreted at the top of the tombstone and the implementation language at the base of the tombstone, an example of an interpreter is shown in Figure 3.3.

A translator or compiler is represented by a T–shaped tombstone with source language at the left, the target language at the right and the imple-

Figure 3.2 A machine running machine code M.

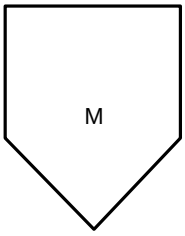


Figure 3.3 An interpreter interpreting P implemented in I.

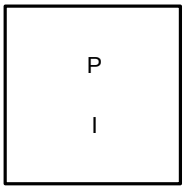
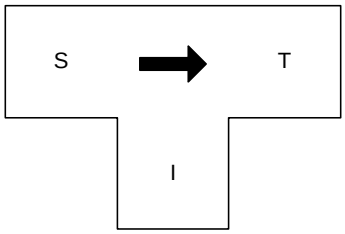


mentation language at the base of the tombstone, an example of a translator is shown in Figure 3.4.

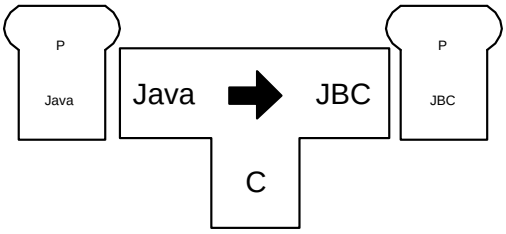
Figure 3.4 A translator translating from S into T implemented in I.



Translation of a program using a translator can be illustrated by putting the program to be translated to the left of the translator and the result to the right of the translator. An example of this is shown in Figure 3.5. The implementation language of the program to the left must match the source language of the translator. The implementation language is then changed by the translator to represent a program with a new implementation language to the right. If a machine or a combination of a machine and an interpreter can execute a language then a program with that implementation language may be executed.

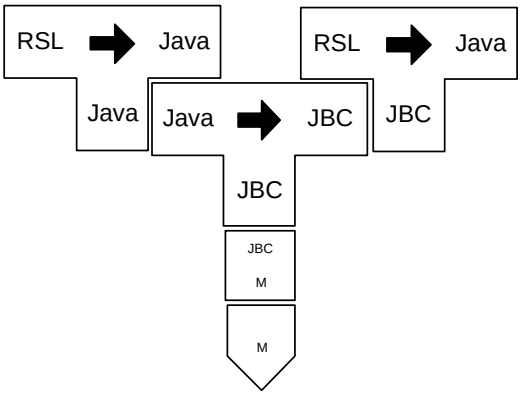
A translator is also a program and may be translated using a translator, which is a program and must be executed using a machine of a combination

Figure 3.5 A Java program P being translated to Java Byte Code (JBC) using a Java to JBC translator implemented in C.



of a machine and an interpreter. An example of this is shown in Figure 3.6.

Figure 3.6 An RSL to Java translator implemented in Java being translated into a RSL to Java translator implemented in JBC, using a Java to JBC translator implemented in JBC interpreted by a JBC to M interpreter on a machine M.

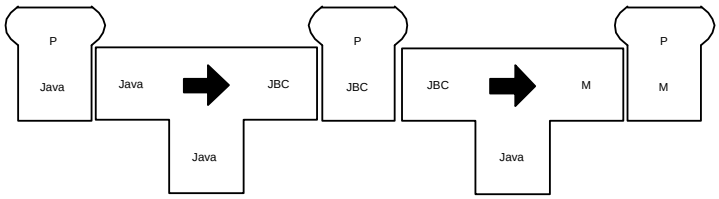


The tombstone diagrams can also be used to describe a multistage compiler by putting the compilers adjacent to each other separated by a program expressed in the intermediate language, an example of a multistage compiler is shown in Figure 3.7.

Full Bootstrapping Process

The full bootstrapping process is used for developing a new compiler from scratch. An advantage of the full bootstrapping process is that at the end of the process, the compiler is expressed in the source language, for which it is developed i.e. maintenance and extension of the compiler do not depend on any other languages. The development of the Java compiler will be used as

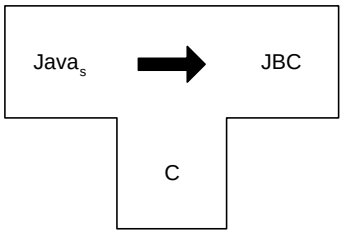
Figure 3.7 A two–stage compiler compiling from Java to M with JBC as intermediate language.



an example. The Java source code comes in different versions in this context. The first version is a small subset which is named Java$_s$. The target language of the compiler is JBC (Java Byte Code). An interpreter for JBC is assumed available, and therefore JBC is assumed to be executable.

The first step of the process is to develop a compiler for the small subset Java$_s$ in a language, for which a compiler is already available. The language used for developing the Java compiler was C [19]. The compiler is shown in Figure 3.8.

Figure 3.8 A compiler for Java$_0$ into JBC implemented in C.



This compiler for Java$_s$ is compiled using the available compiler for the implementation language. The result is an executable compiler for Java$_s$. The compilation is shown in Figure 3.9.

The second step of the bootstrapping process is to write a second version of the compiler. The second version is written in the source language Java$_s$, as shown in Figure 3.10. The second version of the compiler is then compiled using the first version, as shown in Figure 3.11.

The third and final step is to extend the second version of the compiler to the full language. The third version of the compiler is shown in Figure 3.12. The third version is compiled using the second version, as shown in Figure 3.13. The result is a compiler for the full source language written in some subset of the source language. There are no dependencies on other languages. The third version of the compiler may be used to compile new

Figure 3.9 Compilation of the developed compiler.

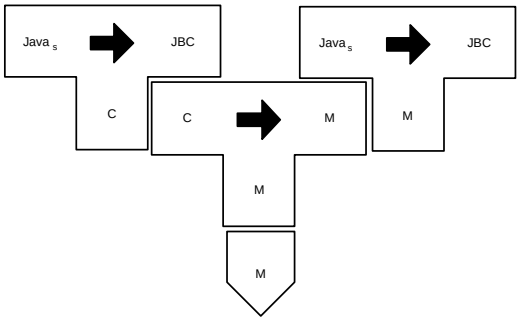


Figure 3.10 Second version of the compiler written in Java_s.

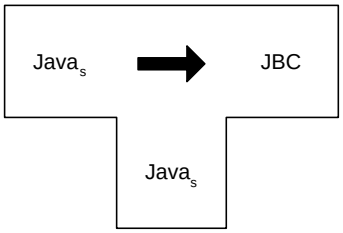

Figure 3.11 Compilation of the second version of the compiler.

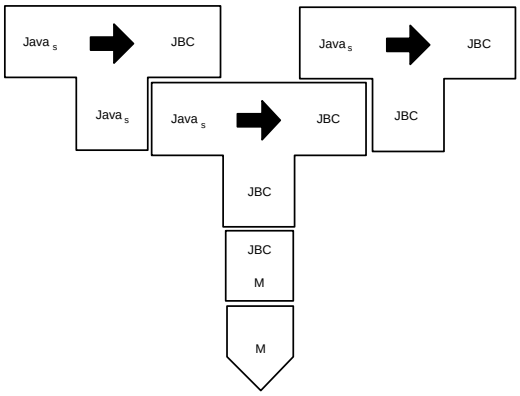

versions of the compiler itself.

Optimization Using Bootstrapping

Bootstrapping can also be used to optimize a compiler. The optimization has two purposes:

Figure 3.12 Third version of the compiler extended to the whole source language.

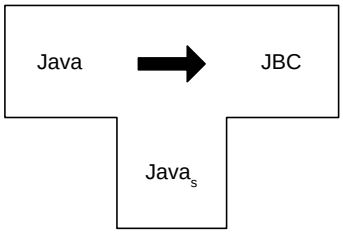

Figure 3.13 Compilation of the third version of the compiler.

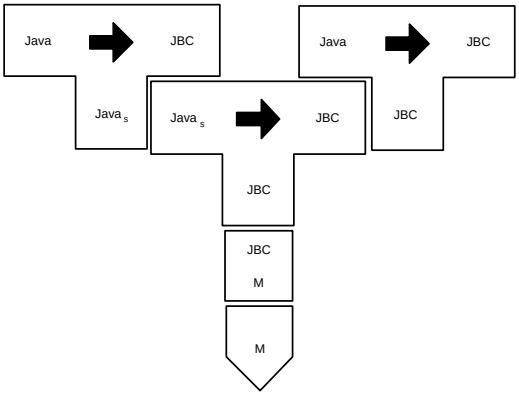

1. Producing better programs, i.e. higher quality of code in the target language.

2. Improving the compiler itself, i.e. the efficiency in the compilation process.

The starting point for the optimization process is a compiler expressed in source language as well as in low quality target language. In this section optimization of an RSL to Java translator will be used as example. Java is assumed to be executable in this context. Both versions of the translators are shown in Figure 3.14. The quality of the target language is indicated by superscript *low* and *high* on the arrow of the translator and as subscript under the tombstone base.

The first step is to modify the first version of the translator implemented in the source language to produce higher quality target language, as shown in Figure 3.15.

The new version of the translator is translated using the executable version of the first translator, which is shown in Figure 3.16.

Figure 3.14 Left: Translator implemented in the source language. Right: Translator implemented in the target language.

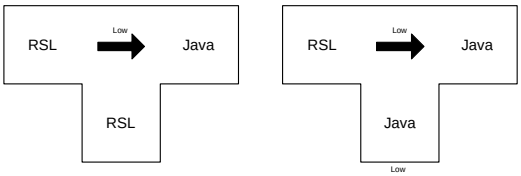

Figure 3.15 The modified translator producing high quality target language.

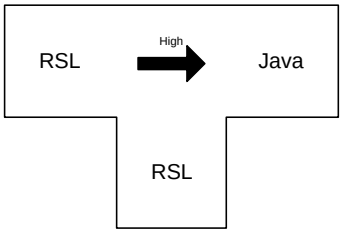

Figure 3.16 Translation of the new version of the translator using the first version.

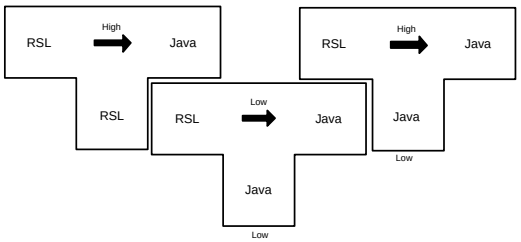


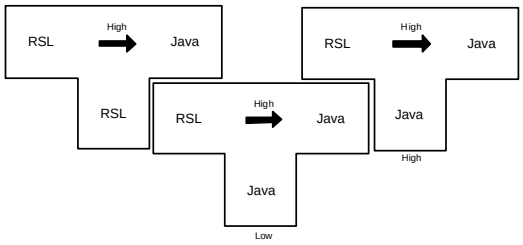
The result of the translation of the second version of the translator is a translator producing high quality target language. However, the executable version of the translator is still implemented in the low quality target language. This is fixed by translating the second version of the translator using the executable version of itself, as shown in Figure 3.17.

The result of this is a translator producing high quality target language implemented in high quality target language.

3.1.2 Design Patterns

"Each pattern describes a problem, which occurs over and over again, and then describes the core of the solution to that problem, in such a way that

Figure 3.17 Translation of the second version of the translation using the second version.



you can use the solution over and over again" [7, p. 2] In software design, this concept applies to several levels of abstraction.

At a low abstraction level, there is often a need for structures to represent data in some way. An example of this is the need to represent data as a list or as a tree. The structures are independent of the actual content of the structure. A list of integers is not very different from a list of real numbers. Therefore general solutions for representing different kinds of lists have been developed as well as methods for operating on these lists. Representation of different kinds of data structures and methods for operating on these structures have been described in numerous places [4].

At a higher level of abstraction, there may be a need for a solution for generating different output from the same input, or to ensure that only one instance of an object exists in an object–oriented language. Solutions for these kinds of design issues have also been described by several authors [7].

In the programming language chosen for this project, namely Java, there are libraries for many kinds of data structures as well as support for operating on them, i.e. solutions of the design issues of the first level of abstraction mentioned. No solutions are implemented for the higher level design issues. Therefore, solutions of these kind of issues must be implemented by hand. The following section deals with the visitor design pattern which will be used in the design of the translator.

Visitor Design Pattern

The purpose of the visitor design pattern is to separate a hierarchical structure of objects from tasks which must be performed on the structure [7]. The standard way to implement a feature in a structure is to add a method for the feature to each object in the structure. Each method carries out the feature for the object and invokes the same method in the subparts in the structure. As an example, a feature for printing a structure is implemented

by adding a print method to each object in the structure. Another feature of the structure is then implemented as another method in each of the objects. There are three problems with this solution:

1. Each feature is spread as methods in all the objects of a structure. This makes it difficult to get an overview of the feature.

2. Addition or removal of a feature requires changes in all objects of a structure. This makes changes in the functionality of a structure tedious.

3. The object hierarchy often represents a hierarchical structure in the real world. The structure has nothing to do with the tasks that must be performed on the hierarchy. It makes the design less clear that the tasks and the structure are mixed together.

The visitor design pattern solves this by moving the methods of the different features into separate task objects. The task objects are called *visitors*. A visitor traverses a structure of objects and completes the task by performing a part of the task while it visits an object. The visitor design pattern works by adding one method to all the classes in the object structure. The method is typically named accept or visit and takes a visitor as argument. The method calls a unique method, named visitObject, where Object is the name of the structure, in the visitor with itself as parameter. It is the unique method in the visitor which performes a part of the task.

One example of such an object structure could be a representation of a questionnaire in a system for doing interviews using a computer. A questionnaire consists of an introduction text and a number of questions. A question consists of a question text and a number of answer options. An answer option consists of a text describing the answer option. This can be represented by three types of objects: a questionnaire object, a question object, and an answer option object. A questionnaire must both be validated and printed, therefore each object contains a method for doing so. The questionnaire structure is shown in Figure 3.18.

In Figure 3.19, the same object hierarchy for an interviewing system is shown implemented using the visitor design pattern. The print and validate methods have been removed from the object structure. A class implementing the visitor interface has been added for each of the features.

Should the need arise for a new feature, it can be implemented as a third visitor in the second solution, whereas it would require addition of a method in each of the classes in the first solution.

The traversal of an object structure implementing the visitor design pattern can be placed in two places: either the traversal can be placed in the

Figure 3.18 Questionnaire–structure without the visitor design pattern.

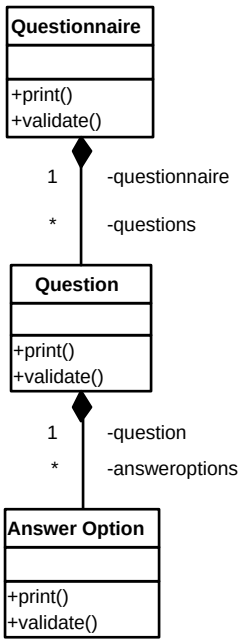


Figure 3.19 Questionnaire–structure with the visitor design pattern.

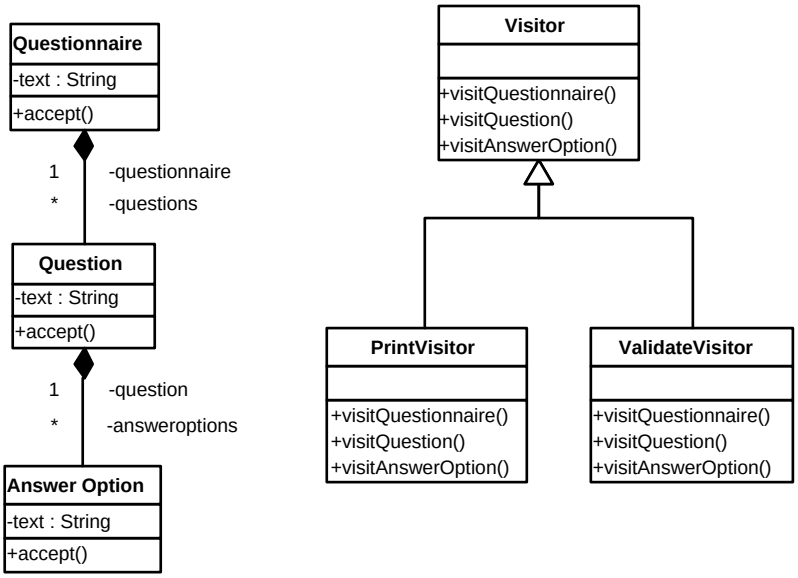


object structure in the accept method, or it can be placed in the visitors. The most simple solution is to keep the traversal in the object structure, because then it is kept in one place and not in all the different visitors. The reason for putting the traversal in the visitors anyway is in case that the traversal are different for the different visitors, or if it is necessary to perform actions, both before and after the traversal of the subcomponents in the visitObject methods.

A simple example of the need to perform actions both before and after the traversal of the subcomponents, is in case of a feature for printing a representation of a block in Java. If the traversal is put into the accept method of the block as shown in Example 3.1, then the call to visitBlock must be done either before or after the *for–loop* running through the statements. The problem with this is that if the call to visitBlock is done before the *for–loop* then there is no place to put the corresponding System.out.println("}"); statement and vice versa. The solution is to place the traversal in the visitor, i.e. the traversal of subcomponents is placed in the visitObject method for each object. This allows the visitor to perform actions both before and after the traversal of the subcomponents. In Example 3.2, the same example of printing a block in Java is shown with the traversal placed in the visitor.

Example 3.1 Visitor pattern – traversal in object structure.

```
public StringVisitor implements Visitor {
    public visitBlock(Block block) {
        System.out.print("{");
    }
}

public class Block implements Element {
    ArrayList<Statement> statementList;

    public void accept(Visitor visitor) {
        visitor.visitBlock(this);
        for(Statement statement : statementList)
            statement.accept(visitor);
    }
}
```

3.2 Architechtural Design of the Translator

The development of a translator between two languages is a complex task. Therefore, the task must be decomposed into smaller parts which can be

Example 3.2 Visitor pattern – traversal in visitor.

```
public StringVisitor implements Visitor {
    public visitBlock(Block block) {
        System.out.print("{");
        for(Statement statement : block.getStatementList())
            statement.accept(visitor);
        System.out.print("}");
    }
}

public Block implements Element {
    ArrayList<Statement> statementList;

    public void accept(Visitor visitor) {
        visitor.visitBlock(this);
    }
}
```

dealt with. The task of translating RSL into Java has been decomposed into three subtasks, each subtask is designed as a module in the translator.

1. Create an abstract representation of RSL based on the RSL given as input. (Front end)

2. Translate the abstract representation of RSL into an abstract representation of Java. (Translation module)

3. Generate Java source code based on the abstract representation of Java. (Back end)

The translation from an abstract representation of RSL into an abstract representation of Java is a considerable task. Based on that, it is decided to let the development of the translation module be incremental.

In order to make the development of the translation module incremental a full bootstrapping process is chosen. This makes it possible to maintain and extend the translation module using RSL, rather than a programming language or some other high level language. The use of a bootstrapping process in the development of one of the modules determines that this module should be implemented by hand in the languages involved in the bootstrapping process.

The next decisions are how to develop the front end and the back end of the translator. The front end may either be implemented by hand or developed using a tool, which generates a lexical scanner and a parser. The

latter solution is chosen, because it is easier to implement and maintain a lexical scanner and a parser in a high level language of a tool, rather than a lexical scanner and a parser implemented by hand.

There are no tools available for creating code based on an abstract tree representation. The abstract representation of Java implements the visitor design pattern. The generation of Java source code from an AST can therefore be implemented as a visitor.

The three modules involved in the translation process are controlled by a fourth module (Control module), which takes care of input and output as well as controlling the translation process.

To make the design clear, the interfaces between the different modules should be clear. There are four kinds of data, which flow in the translator, they are listed below:

1. RSL – One or more files written in the ASCII representation of RSL.

2. RSL AST (Abstract Syntax Tree of RSL)[1] – An instance of a class in Java along with the classes used by it.

3. Java Ast (Abstract Syntax Tree of Java) [2] – An instance of a class in Java along with the classes used by it.

4. Java – One or more files written in Java source code.

The interface between the modules are made clear by letting each of the modules take care of a transformation between two of the data structures.

The flow of translation is illustrated in Figure 3.20. The figure shows the three modules involved in the translation as well as the representations of data in the different stages of translation.

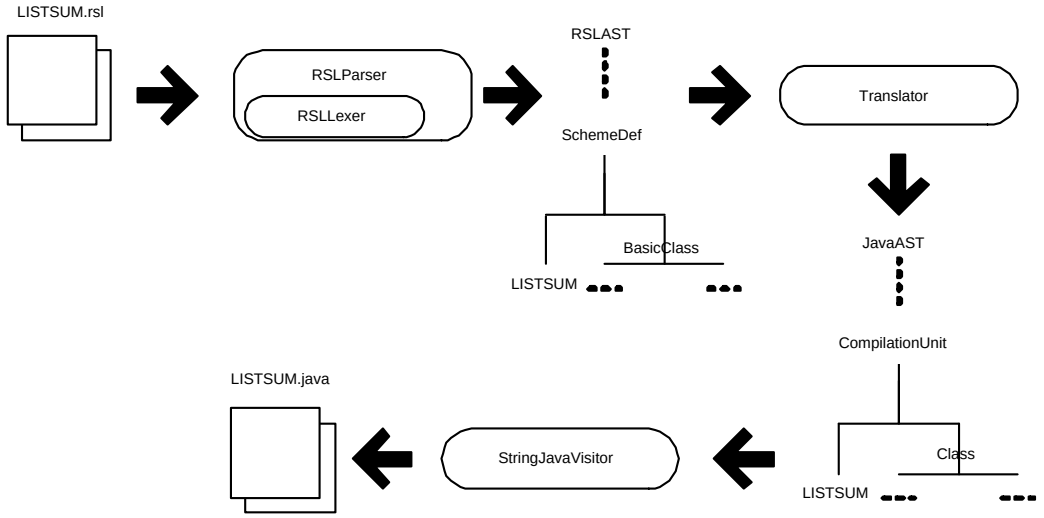
3.2.1 Data Structures

Data Structure RSL

RSL in this context is one or more files written in the ASCII representation of RSL according to [11]. Furthermore, the RSL used in the specification must be within the subsets described. The subsets are presented in Section 3.4.

[1] The term Abstract Syntax Tree (AST) is explained in Section 3.2.2
[2] The term Abstract Syntax Tree (AST) is explained in Section 3.2.2

Figure 3.20 Flow of translation.



Data Structure RSL AST

The data structure for representing RSL in the translator is an abstract syntax tree. The tree is implemented as a number of classes in Java, which all inherit from a base class containing a few common properties, namely a field for the parent node and a field for the type of the node. The data structure implements the visitor design pattern for traversing the tree. A concrete representation of an RSL specification is an instance of the top class. The structure of the RSL AST is based on the syntax found in [11, Appendix A]. Furthermore the definition of test cases has been allowed using the syntax described in [1].

Data Structure Java AST

The data structure for representing Java in the translator is also an abstract syntax tree. The tree is implemented as a number of classes in Java, which all inherits from a base class. This data structure also implements the visitor design pattern for traversing the tree. A concrete representation of Java is an instance of the top class of the hierarchy. The structure of the Java AST is based on the syntax found in [13, Appendix L] and [5].

Data Structure Java

Java in this context is one or more files written in Java source code. The source code generated uses some of the new features added in Java 1.5.0. In

Figure 3.21 Lexical analysis of if–then–else statement in RSL.

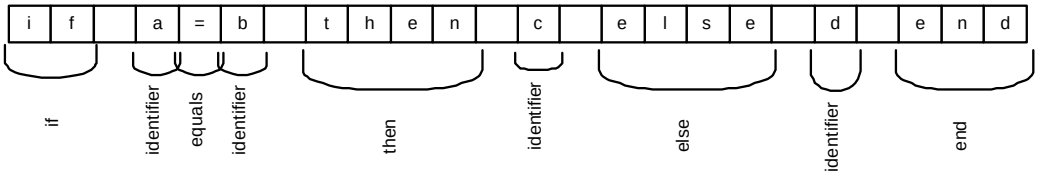


Figure 3.22 Parsing of if–then–else statement in RSL.

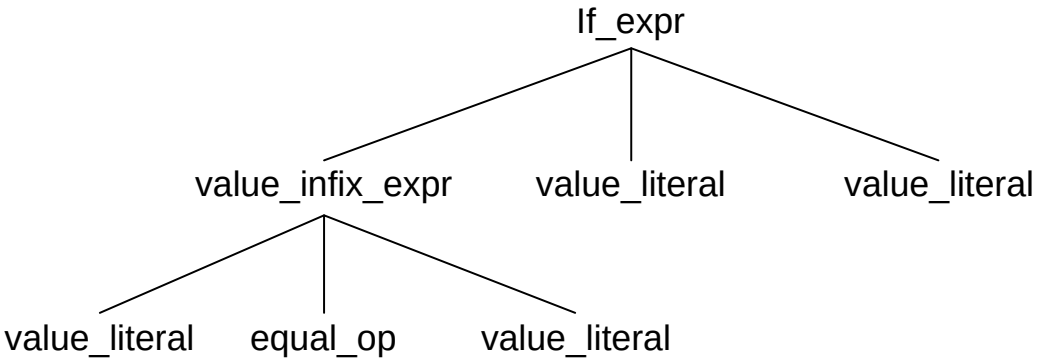


order to be able to use the output of the translator, one must have at least J2SE 5.0 (Java 1.5.0 SDK) or a later version installed.

3.2.2 Front End of the translator

As stated in Section 3.2, the front end should be developed using a tool. The front end in this context covers two phases of the translation process, namely lexical analysis of RSL and parsing RSL into an abstract syntax tree representation of RSL.

The lexical analysis is done by a lexical analyzer. A lexical analyzer, often referred to as a lexer, reads the input one character at a time and combines them into groups of characters having a collective meaning, known as tokens, an illustration of this is shown in Figure 3.21.

A parser creates an abstract syntax tree from the tokens passed on by the lexical analyzer. An abstract syntax tree is a tree representation of constructs in the source language where unnecessary information has been removed, this is shown in Figure 3.22. The keywords “if”, “then”, “else” and “end” has been removed. They are not necessary, because the node of the tree is if_expr node and it is the content of the if–then–else expression that is interesting.

Several tools were considered for the development of the front end. They

are presented in following section along with reasons for using or not using the tool.

Tools Considered

The tools considered are:

- Gentle [17]
- Lex & Yacc [8]
- SableCC [9]
- Javacc [3]
- ANTLR [14]

The first tool, Gentle, was considered, because several other tools for RSL have been developed using Gentle. These tools where developed entirely using Gentle. In this project, only a part of the translator should be developed using a tool. Gentle is not well suited for generating a part of a compiler, because Gentle generates a set of specifications, which are then processed by Lex & Yacc. The two phases of Gentle make it hard to see the correspondence between the specification provided for Gentle and the resulting source code generated by Lex & Yacc. The source code generated by Lex & Yacc is C. Therefore, some port of Gentle to Java was needed, in order for it to be part of a bootstrapping process with Java as target language. This should be possible since Lex & Yacc are ported to Java, but it represents a considerable task in itself.

The second option considered was Lex & Yacc, because they are almost synonymous with generation of compilers. The original tools were not considered, but ports of them to Java were. They were not selected, because of the better possibilities for specifying rules using EBNF[3] for the parser in some of the other tools.

SableCC was considered because it provides tools for traversing the AST generated. SableCC was not selected, because it is not possible to control the generation of the AST. Full control over the generation of the AST is needed to integrate between the front end and the bootstrapped translation module. The reason for this is that in order for a translation module specified in RSL to be type checked using the existing tools, the types used in the specification must be in the context of the specification, i.e. the data structures RSL AST

[3]See [6] p. 37.

and Java AST must be specified in RSL. Therefore, full control over the types used in the AST in the front end is needed.

The last two tools considered were Javacc and ANTLR. They are very similar in their interface. It is possible in both tools to specify rules using EBNF both for the lexical scanner and the parser. They both have a possibility for generating an AST and for adding action code to each rule in the grammar. ANTLR was preferred, because it is based on open source and it is more widely used than Javacc. ANTLR is furthermore better documented than Javacc.

ANTLR was chosen as tool for this work because it provides the best features.

3.2.3 Translation Module

The task of the translation module in the translator is to do a translation from an RSL AST into a Java AST. This is done in two steps.

1. A number of passes over the RSL AST to decorate it with types.

2. Create a Java AST based on a RSL AST.

Type Decorating the RSL AST

Before creating a Java AST the RSL AST has to be decorated with types. There are two reasons for this:

1. According to the translations specified in Chapter 2 several constructs in RSL must be translated to a number of different expressions in Java depending on the context and the parts involved.

2. The empty list requires a typing in Java.

An example of a construct, which requires different translations, is the application expression in RSL. In Example 3.3 a number of application expressions are listed in the test cases. The translation of these are presented in the listing of code in the example. The Java source code shows that the application of `mk_MyShortRecordDefinition` is translated as a class instance creation expression in Java, while the application of the function `myFunction` is translated as a method invocation of a method in Java. The application of `myList` is translated as a method invocation of a method on an object in Java. In order to handle these expressions differently, even though they are all application expressions, they must be decorated in some way.

Example 3.3 Different kinds of application expressions in RSL.

type
MyVariantDefinition == Alternative1,
MyShortRecordDefinition :: variant : MyVariantDefinition
value
myList : **Text*** = ⟨″a″, ″b″⟩,
myFunction : **Real** → **Real**
MyFucntion(r) ≡ r + 1.0
test_case
[1] mk_MyShortRecordDefinition(Alternative1),
[2] myList(1),
[3] myFunction(myFunction(5.0))

```
/* Translation of types and values omitted. */
public static void main(String[] args) {
    System.out.println("[t1]: " + new
      MyShortRecordDefinition(new Alternative1()));
    System.out.println("[t2]: " + myList.get(1));
    System.out.println("[t3]: " +
      myFunction(myFunction(5.0d)));
}
```

The passes over the RSL AST are done by a number of visitors. The first visitor passing over the RSL AST is a *ParentVisitor*, which takes care of setting the parent of each node in the RSL AST. One could argue, that this could have been done in the creation of the RSL AST in the front end. This would have lead to more complex action code in the grammar file of the front end. The second and third pass over the RSL AST is done by a *TypeDecorateVisitor*, which tries to determine the type of an expression, and, if successful, sets the type of the expression.

The reason that a typing of the empty list is required is somewhat complex. The translation of a list in RSL is an instance of the RSLListDefault<E> class in Java. The class in Java is a generic class which needs a typing. It is possible to use an untyped list if it is used as argument to a method in Java, but it is not possible to use an untyped list as argument to a constructor. Therefore all lists must be typed, even if they are empty.

In Example 3.4 an explicit function definition with a value expression containing two empty lists is shown. There is an empty list in the condition of the if–then–else expression, and there is an empty list in the if–branch of the if–then–else expression.

To determine the type of the empty list in the condition of the if–then–else expression, the *TypeDecorateVisitor* looks at the parent expression. The parent expression is a value infix expression using the equal operator. The syntax rules of RSL dictate, that both operands of a value infix expression must be of the same type if the operator is the equal operator. The type of the empty list in the condition can therefore be set to the type of the left–hand side operand. The type of the left–hand side operand is known, because it is a parameter of the function, where the type can be determined from the function type expression and the binding list.

To determine the type of the empty list in the if–branch the fact that each branch of an if–then–else expression must have the same type is used. The type of the else–branch of the if expression can be determined by determining the type of the value infix expression. The type of the value infix expression is determined by looking at the operator and the operands. In case of an operator for which the type of the result is the same as the operands, the type of the value infix expression can be set by determining the type of the operands. In Example 3.4 the operator of the value infix expression is the concatenation operator. The result of the concatenation operator is a list or a text, which is a list of **Char**. The operands of the concatenation operator must also be lists of the same type. The type of both value infix expression as well as the operands can be set, because of the type of the operands of the value infix expression is known. This means that the type of the else–branch and therefore the if–branch can be set.

Example 3.4 LISTMULT example.

listmult : **Int*** × **Int** → **Int***
listmult(il, i) ≡
  if il = ⟨⟩ **then**
    ⟨⟩
  else
    ⟨ **hd** il ∗ i ⟩ ⌢ listmult(**tl** il, i)
  end

```
public static RSLList<Integer> listmult(RSLList<Integer> il,
                                        int i) {
    if(il.equals(new RSLListDefault<Integer>())) {
        return new RSLListDefault<Integer>();
    }
    else {
        return ((new RSLListDefault<Integer>(il.hd() * i)).
                concat(listmult(il.tl(), i)));
    }
}
```

Creating a Java AST From a Decorated RSL AST

The translation from an RSL AST to a Java AST is done by a number of functions working from the top of the RSL AST to the bottom. The functions rely on recursion for running through the lists in the RSL AST. The reason for using recursion rather than iteration is that it is possible to use recursion both in Java and in the subset of RSL translated.

The top level function for doing the translation takes an RSL AST as argument and returns a Java AST. The functions works by calling other functions based on, what is needed at the place in the Java construct. A Java AST consist of a collection of compilation units. Therefore, two methods creating a number of compilation units from an RSL AST is called. The results of these two are joined and the Java AST is created. One of the compilation units is the translation of the scheme being translated. A compilation unit consists of a class declaration, which again for one part consists of a list of methods. The list of methods in the compilation unit is created by a method which runs through the declarations of the basic class expression of the scheme being translated and creates method declarations corresponding to the functions in the declarations.

The principle is that the structure of the components in the Java AST is known, and the functions create these structures based on the information

which may be found in the RSL AST. An example of this could be the translation of an explicit function definition. An explicit function definition is translated as a method declaration according to Section 2.4.2. A method declaration in Java consists of the following components:

1. A list of modifiers.
2. A name.
3. A return type.
4. A list of arguments
5. A block determining the output.

These fives items are needed to create a valid method declaration in Java. The top–level method for translating an explicit function definition does this by creating a method declaration and letting a number of auxiliary methods create the parts needed. One method creates a name for the method from the id of the explicit function definition in RSL. A second method creates the list of arguments for the method based on the binding list and the type expression in RSL. A third method determines the return type for the method from the type expression of the explicit function definition. A fourth method creates a block from the value expression of the explicit function definition.

3.2.4 Back End of the translator

The back end of the translator, i.e. the part transforming the Java AST to concrete Java source code is implemented by hand as a visitor. The Java AST implements the visitor design pattern for traversing the tree. Normally the back end of a translator performs code generation as well as optimization of the code, before it is written to files. In this solution the back end is only responsible for writing the Java source code from the Java AST. The optimization should be done in the translation module. The reason for not letting the back end do any changes to the code is that by keeping this in the translation module, the optimizations may be specified using RSL rather than implemented by hand in Java.

3.2.5 Control Module

The purpose of the control module is to bind the other modules together and to be interface to the users of the translator. The control module should instantiate the other modules and pass the data structures to the modules.

In order to make the implementation of the control module easy, it should complete one stage of the translation before starting the next stage.

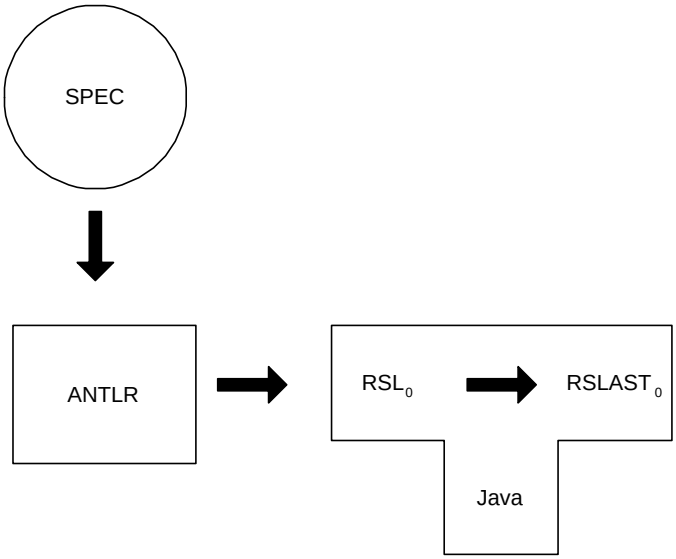
3.3 Development Process

The translation module of the translator is developed using a full bootstrapping process. This means that the translator will be developed stepwise. This section gives an overview of the steps and components involved in the bootstrapping process in the development of the translator. The translator is divided into three modules. Each module takes care of one stage in the translation process. The steps and modules will be illustrated using tombstone diagrams.

The development of the translator from RSL into Java source code assumes that there is a compiler from Java to Java byte code and an interpreter for the machine used available, i.e. it assumes that J2SE SDK is available for the platform. The translation from Java into Java byte code and interpretation of the byte code on the machine has been omitted from the diagrams. When a program or a translator has Java as implementation language it is assumed to be executable in this context.

The first step is to develop a translator which translates a small subset of RSL into Java. Figure 3.23 illustrates the use of ANTLR to create a trans-

Figure 3.23 Using ANTLR.



lator translating from RSL_0 to $RSLAST_0$, which is the AST representation of RSL_0.

Figure 3.24 Front end: Tool translating from RSL_0 to $RSLAST_0$.

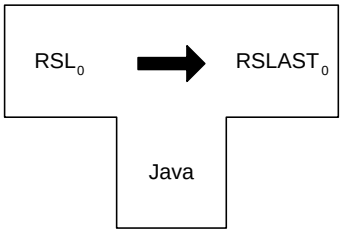


Figure 3.24 illustrates the result of using ANTLR on a specification of the syntax of RSL_0, i.e. the front end of the translator.

Figure 3.25 Translation Module: Tool translating from $RSLAST_0$ to JavaAst.

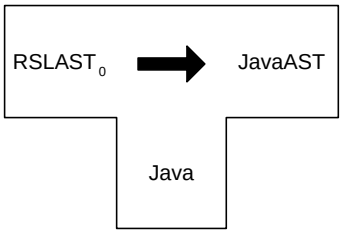

Figure 3.25 illustrates the translation module implemented by hand, which translates between the two abstract representations of the languages.

Figure 3.26 Back end: Tool for generating Java from the JavaAst.

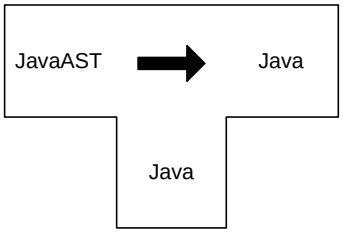

Figure 3.26 illustrates the module implemented by hand, which translates from the Java AST into Java source code, i.e., the back end of the translator.

These three modules can be combined into a three–stage translator. The flow of a program being translated is shown in Figure 3.27.

Figure 3.27 Combining the parts to a translator from RSL_0 to Java.

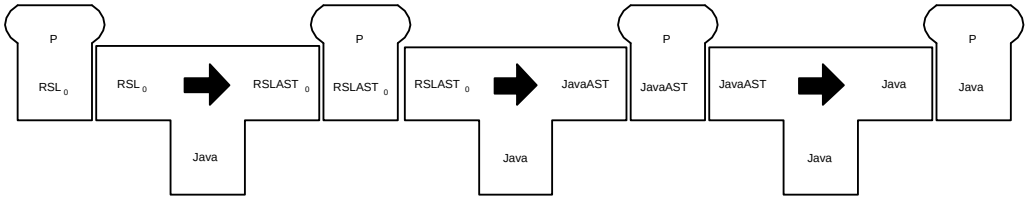

Figure 3.28 Result of combining the parts.

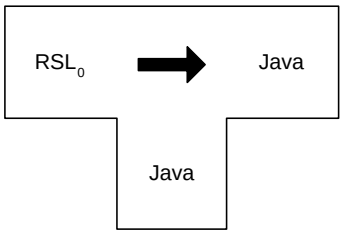

The three–stage translator can be viewed as one translator from RSL_0 to Java source code, as shown in Figure 3.28. This concludes the first step of the bootstrapping process. The result of this step is, as shown, a translator translating from RSL_0 into Java where each module is implemented by hand. This version of the translator is referred to as the "first version of the translator".

The second step of the bootstrapping process is to create a specification of a translation module from $RSLAST_1$ into JavaAST using RSL_0 as implementation language. The new module is shown in Figure 3.29, and the specification in RSL may be found in appendix C.1.1. Furthermore, the RSL AST must be modified to integrate with the new version of the translation module. At this point the $RSLAST_1$ could be extended to the full RSL language to avoid having to change it further in the next step. This was not done in this project, but it is suggested as the first point of an extension to this project in Chapter 7.

The translation module specified is made executable by first translating the specification developed using the translator developed in the first step. The translation is shown in Figure 3.30. This results in a new translation module translating from $RSLAST_1$ to JavaAST.

The new translation module is then combined with the modified front end and the back end into a new three–stage translator translating from RSL_1 into Java source code, as shown in Figure 3.31.

The new three–stage translator can be viewed as one translating from

Figure 3.29 Specification of a new translation module.

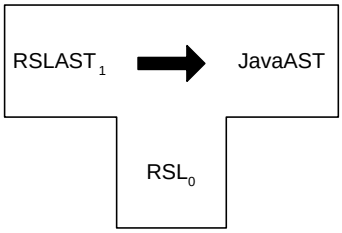

Figure 3.30 Translating the specification using the first version of the translator.

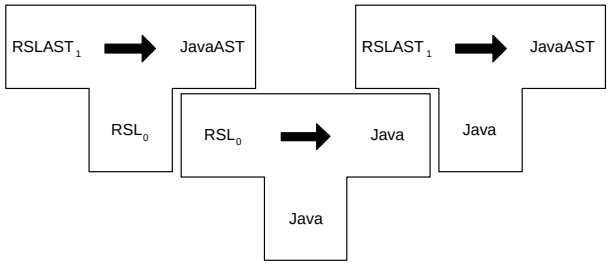

Figure 3.31 Combining the new translation module with the front end and back end.

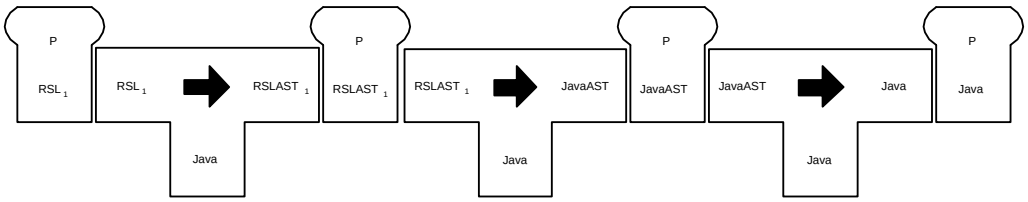
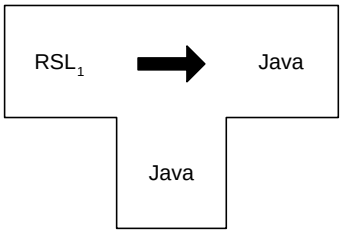


RSL_1 to Java implemented in Java, see Figure 3.32.

Figure 3.32 Result of combining the new parts.



This concludes the second step of the bootstrapping process. The result is

a new translator which handles a slightly larger subset of RSL. This version of the translator is referred to as "the second version of the translator". The front end and the back end is only modified slightly by hand to fit the new constructs. The conclusion is that only a few modifications in Java are needed, while the main work in this step is done in RSL.

At this point, one can keep expanding and optimizing the translation module by specifying the new version in RSL_{n-1}. The specification can then be translated using the three–stage translator of the previous step. The translated specification can then be combined with the front end and the back end into a new three–stage translator translating from RSL_n to Java source code.

3.4 Subsets of RSL

The decision of using a bootstrapping process adds an extra dimension to the process of determining which subset of RSL to translate. It must be determined what the subset should be in the different steps of the bootstrapping process. To avoid doing too much of the implementation of the translation by hand the first subset of RSL, named RSL_0, should be as small as possible, yet strong enough to get the process started. It should be possible to specify a translation module using RSL_0.

3.4.1 Description of RSL_0

The RSL_0 subset of RSL only contains what is needed for some examples and for a specification of a translation module. The fact that the second version of the translation module must be specified in this subset sets some requirements of what is needed in RSL_0.

To be able to specify the translation module the types used in the translation module must also be specified in RSL. The types used in the translation module are the two AST representations of the languages. In order to specify the abstract syntax tree for a language, it is necessary to be able to define a type which has several alternatives as an example to specify that there is an infix operator which may be a number of different operators. Furthermore, one must be able to define that a construct consist of several other constructs, as an example to specify that an explicit function definition consists of among other things a type expression and a value expression. These two requirements mean that variant definitions are required in RSL_0. The variant definitions allow for a specification of several alternatives and the record constructors in variant definitions allow for a specification of that an

alternative may consist of several other constructs. To make variant definitions with one alternative simpler to define, short record definitions should also be included. Some constructs in RSL may contain a number of other constructs of the same type. As an example the variant definition may have a number of alternatives. To specify this lists must also be added to RSL_0. To handle simple examples the built–in types in RSL must be added, except for **Nat** which is a subtype of **Int**.

In order to be able to manipulate the two AST's defined, and to create one from the other, functions are needed. Therefore, explicit function definitions are part of RSL_0. Functions in a translation module are quite complex, so they must be able to take more than one parameter. Therefore, product type expressions in the first part of a function type expression is allowed. However, to make the implementation simple, multiple outputs from functions are not permitted. The outcome of an explicit function is described by a value expression. Therefore, a number of value expressions must be selected to define the outcome of functions.

In order to be able to make choices and differentiate between the different alternatives of a variant definition, case expressions and if expressions are part of RSL_0. Furthermore, it must be possible to manipulate the lists allowed in RSL_0, therefore prefix expression using the list operator **hd** and **tl** are also part of RSL. To cope with simple examples using the built–in types and to be able to combine lists and compare different value expressions, value infix expressions using $+$, $*$, $\hat{}$ and $=$ are part of RSL_0. In order to be able to call functions recursively, call other functions, construct records using constructors and make functions of short record definitions, application expressions are also part of RSL_0.

All these functions, and types which are needed in order to define a specification of a translation module must be put in some kind of module in order for them to be valid RSL. Furthermore, it would definitely be an advantage if the specification could be divided into several modules, because a specification of a translation module is quite large. These requirements mean that schemes and some kind of extend should be allowed in RSL_0, in order to divide the specification into several modules.

Overview of RSL_0:

- Top level constructs:
  - Schemes using the class expressions allowed. Parameterization not allowed.

  - Class expression:
    * Basic class expression using the declarations allowed.
    * Extending class expression with the base class as a scheme instantiation.
    * Scheme instantiations in an extending class expression.

- Type definitions:
  - Short Record definitions; destructors are required, reconstructors are not allowed.
  - Variant definition; destructors are required, reconstructors are not allowed.

- Value definitions:
  - Explicit function definitions using an id application and not products as result, using the value expressions allowed.

- Test case definitions using the value expression allowed. The test cases in RSL_0 must include an identifier.

- Type Expressions:
  - Function type expression. Only in form of total functions using the other type expression described as domain, and a function result description containing any of the other type expressions except product and function type expressions.
  - List type expression.
  - Product type expression as part of the domain of a function type expression.
  - Type literals excluding **Nat**.

- Value Expressions:
  - Value infix expressions using $\hat{}$, $=$, $+$ and $*$.
  - Value prefix expressions using **hd** and **tl**.
  - Enumerated list expressions.
  - Value or variable names.
  - Application expressions.
  - Structured expressions:

    - Case expressions using name, literal and record patterns
    - If expressions not containing **elsif** statements
  - Value literals.

3.4.2 Description of RSL_1

The RSL_1 subset of RSL is the next subset after RSL_0. This would be the point, where one tried to add as many features of the source language as possible. In this work, however, only one feature has been added namely the division operator for value infix expression. The reason for this is that the second step of the bootstrapping process in this project is only to prove that it is possible to get the process started. In Chapter 7 suggestions for how to extend the translator to a larger subset are given.

Chapter 4

Implementation of the Translator

This chapter describes some of the details of the implementation of the translator. It starts, in Section 4.1, with an introduction to the library classes developed for representations of lists, sets and maps. Afterwards, in Section 4.2 and 4.3, there is a presentation of the two versions of the translator implemented in this project.

4.1 The Library Classes

A number of library classes are implemented, which are common to all versions of the translator. These classes are used in the translation of three of the complex types in RSL, namely: Lists, sets and maps.

The classes and interfaces are grouped in a package named *translator.rsllib*, which is imported into the different versions of the translator. The package contains three interfaces and three classes:

1. *RSLList* – Interface, source code can be found in Appendix E.2.1.
2. *RSLListDefault* – Class, source code can be found in Appendix E.2.2.
3. *RSLSet* – Interface, source code can be found in Appendix E.2.3.
4. *RSLSetDefault* – Class, source code can be found in Appendix E.2.4.
5. *RSLMap* – Interface, source code can be found in Appendix E.2.5.
6. *RSLMapDefault* – Class, source code can be found in Appendix E.2.6.

Each of the three interfaces contains methods corresponding to the operators of the complex type it represents. The three classes are implementations of these interfaces.

The interfaces and classes relies on the generic feature introduced in Java 1.5, which makes it possible to define which type of objects that may be stored in a collection. This feature removes the need for type casting when retrieving an object from a collection. Another feature, which was added in Java 1.5 is boxing and unboxing of primitive types, which removes the need for wrapping a primitive type in a wrapper class, when an object is needed and unwrap a primitive type from a wrapper class, when a primitive type is needed.

Two listings of code are shown in Example 4.1. The two examples show an *ArrayList* of *Integer*'s. The first listing is written in code complying to Java 1.4, whereas the second listing is written in code complying to Java 1.5.

Example 4.1 Generic types, boxing and unboxing in Java 1.5.

Java 1.4

```
ArrayList al = new ArrayList();
al.add(new Integer(5));
al.add(new Integer(6));
System.out.println("al(0) + al(1): " +
  (((Integer)al.get(0)).intValue() +
  ((Integer) al.get(1)).intValue())
);
```

Java 1.5

```
ArrayList<Integer> al = new ArrayList<Integer>();
al.add(5);
al.add(6);
System.out.println("al(0) + al(1): " + (al.get(0) + al.get(1)));
```

The three default classes are implemented using a different kind of collection in the *java.util* package for each of them. *RSLListDefault* is based on an *ArrayList*, *RSLSetDefault* is based on a *HashSet* and *RSLMapDefault* is based on a *HashMap*. All the classes are implemented so that a method returning a new complex type returns a modified shallow copy of the old one. A shallow copy in this context is a new instance of a class in Java containing references to the same objects.

The use of *ArrayList* as base for *RSLListDefault* is not an optimal solution, because the values in a list are not changed in RSL, therefore it is not necessary to create copies of a list – not even shallows copies to create the tail of a list. A linked list would be a more efficient choice. However, the

linked list must be implemented from scratch because the *LinkedList* class in the *java.util* package does not provide options for taking subsequences or the tail of a list. The *LinkedList* class in Java does implement a removeFirst method, but the method is destructive and cannot be used for implementing the **tl** operator on lists. A better solution would be an implementation of a linked list, in which it is possible to create a subsequence just by returning a reference to an object somewhere in the list. In Java, exists a class, *Vector*, which contains a method for creating a sublist, but the *Vector* class is based on an array, therefore, this not an effective solution either, for the problem described.

The implementation of the methods in the interfaces are straightforward and uses the methods defined in the underlying collections for most of the work. An example of the way of implementing the methods of the *RSLList-Default* class using the methods in the underlying collection is the implementation of the hd. hd uses the get method of *ArrayList* for returning the first element of the list. This method is listed in Example 4.2.

An example of the use of shallow copying is the tl method in the *RSLList-Default* class which creates a new *ArrayList* (list2) of the elements i.e. a new list of references to the elements in the old list. Then tl creates a new instance of *RSLListDefault* (result) and set the internal list of result to list2 and removes the first item of the list2 . The method is listed in Example 4.2.

Example 4.2 `hd` and `tl` methods in class: *RSLListDefault*

```
private ArrayList<E> list;

public E hd() {
    return list.get(0);
}

public RSLListDefault<E> tl() {
    ArrayList<E> list2 = new ArrayList<E>(list);
    RSLListDefault<E> result = new RSLListDefault<E>();
    result.list = list2;
    result.list.remove(0);
    return result;
}
```

One of the more complex methods in the library classes is the method compose in the *RSLMapDefault* class, which corresponds to the map composition operator in RSL. This method is listed in Example 4.3. The method does not use the generic feature of Java 1.5.0. The reason for this is that three types are involved in compose, namely:

1. The type of the domain of the inner map.

2. The type of the range of the inner map, which is equal to the type of the domain of the outer map.

3. The type of the range of the outer map.

This cannot be done using the generic feature in Java, which only allows use of the types specified in the signature of the class. Only two types are specified for *RSLMap*, namely the type of the domain and the type of the range of the map. The idea of the compose operator in RSL is to create a new map from the domain of the first map to the range of the second map. An entry in the new map is created if a value in the range of the first map can be found in the domain of the second map. In Java, this is done by creating a new instance of *RSLMapDefault*, which is returned as result. Before returning the *RSLMapDefault* instance there is an iteration over the entry set of the inner map. For each entry in the inner map, it is checked, whether the value of the entry is a key in the outer map (the instance on which the method is applied). If the value of the entry is a key in the outer map, then an entry is added to the result with the key of the entry as key, and the value of applying the value of the entry to the outer map as value.

Example 4.3 compose method in class: *RSLMapDefault*

```
private HashMap<K,V> map;

public RSLMap compose(RSLMap innerMap) {
    RSLMap result = new RSLMapDefault();

    Iterator iterator =
        innerMap.getMap().entrySet().iterator();
    while(iterator.hasNext()) {
        Map.Entry elem = (Map.Entry) iterator.next();

        if(this.map.containsKey((K)elem.getValue())) {
            result.getMap().put(elem.getKey(),
                                (V)this.map.get(innerMap.get(
                                    elem.getKey())));
        }
    }
    return result;
}
```

4.2 First Version of the Translator

The first version of the translator, which translates RSL_0 into Java was implemented entirely by hand in Java. This was needed to get the bootstrapping process started. The translator consists of three modules, which take care of the translation process, and a control module. Two of the data structures, namely the RSL AST and the Java AST, were also implemented by hand. To organize these modules and data structures, a number of packages were created:

translator Package containing the other packages, the translation module, and the control module.

translator.rsllib Package containing library classes for representations of lists, sets, and maps.

translator.lib Package containing visitors for traversing the two AST's and common interfaces and classes for the data structures.

translator.javaast Package containing classes for creating a Java AST.

translator.rslast Package containing classes for creating an RSL AST.

translator.syntacticanalyzer Package containing the grammar file and files generated by ANTLR for the front end of the translator.

The first version of the translator was implemented by hand and the library consist of 9482 lines of code. In addition to this, the lexer and parser generated by ANTLR consist of 3421 lines of code. The source code for the first version of the translator and the library classes can be found in Appendix E.

4.2.1 AST Representation of RSL

The AST representation of RSL was, as stated, implemented by hand in the first version and placed in a package, *translator.rslast*. The package contains a large number of classes, which represent different constructs in RSL. There are a number of correspondences between the syntax rules of RSL presented in [11] and the classes implemented. These correspondences will be listed in the following.

A non–terminal symbol of the grammar is implemented as one or more classes depending on the number of alternatives of the right–hand side of the grammar rule for the non–terminal.

If several non–terminal alternatives exist an abstract class is created, and each of the alternatives is implemented as a class extending the abstract class. An example of such a non–terminal is a type definition in RSL which is shown in Example 4.4.

Example 4.4 Syntax rule *type_def* and corresponding Java implementation.

$$
\begin{aligned}
type\_def ::= \\
&\quad sort\_def \mid \\
&\quad variant\_def \mid \\
&\quad short\_record\_def \mid \\
&\quad abbreviation\_def \mid \\
&\quad union\_def
\end{aligned}
$$

Implemented in the following classes in Java:

```
public abstract class TypeDef {...}
public class SortDef extends TypeDef {...}
public class VariantDef extends TypeDef {...}
public class ShortRecordDef extends TypeDef {...}
```

The rest of the type definitions were not implemented because they are not part of RSL_0.

A right–hand side of a non–terminal symbol which consists of several other symbols is implemented as a class with a number of fields corresponding to the non–terminal symbols of the right–hand side of the rule.

The syntax uses two postfixes on the constructs: *string* and *list*. *string* is a whitespace separated list of a construct, and *list* is a comma separated list of a construct. Both these kind of lists are implemented using the library class provided namely *RSLListDefault*.

An example of such a non–terminal is the *application_expr*. An *application_expr* consist of a *value_expr* and an *optional-value_expr-list* in RSL_0, the rule and the implemention is shown in Example 4.5.

If the right–hand side of a non–terminal consists of only terminal symbols, the non–terminal is implemented as a class with a constant corresponding to each of the terminal symbols. An example of this is the *infix_op* rule, which is shown in Example 4.6.

The RSL AST implements the visitor design pattern as described in Section 3.1.2. More precisely, it implements the variant of the design pattern where the traversal of the structure is placed in the visitor. The source code for the classes implementing the RSL AST can be found in Appendix E.3.

Example 4.5 Implementation of non–terminal containing other non–terminals.

$$\begin{aligned} \mathit{application\_expr} ::= & \\ & \mathit{value\_expr} \\ & \text{optional} - \mathit{value\_expr} - \mathit{list} \end{aligned}$$

Implemented in Java in the following class:

```
public class ApplicationExpr extends ValueExpr implements
    Element {
    private ValueExpr valueExpr;
    private RSLList<ValueExpr> optionalValueExprList;

    public ApplicationExpr(ValueExpr valueExpr,
                           RSLListDefault<ValueExpr>
                              optionalValueExprList) {
        this.valueExpr = valueExpr;
        this.optionalValueExprList = optionalValueExprList;
    }
    ...
}
```

4.2.2 AST Representation of Java

The AST representation of Java was implemented by hand in the first version of the translator. The implementation was based on two sources, namely [13, Appendix L] and [5]. The implementation uses the same principles as the implementation of the RSL AST. A non–terminal symbol whose, right–hand side consists of several non–terminal alternatives is implemented as an abstract class with a number of class extending it. An example of such a construct is the *statement* in Java, which may be a number of different statements. The rule and the implementation is shown in Example 4.7.

If the right–hand side of a non–terminal with one alternative consists of several non–terminals, it is implemented as a class with a number of fields, corresponding to the non–terminal symbols of the right–hand side. An example of this is the *if–statement* in Java, which is shown in Example 4.8.

A right–hand side of a non–terminal consisting of several alternatives, which are all terminal symbols, is implemented as a class containing a constant for each of the alternatives. An example of this is the *modifier* in Java, which is shown in Example 4.9.

The Java AST implements the same variant of the visitor design pattern

Example 4.6 Implementation of non–terminal containing only terminal symbols.

$$
\begin{aligned}
infix\_op ::= & \\
& + \mid \\
& = \mid \\
& \star \mid \\
& \frown
\end{aligned}
$$

Implemented in Java in the following class:

```
public class RSLInfixOp extends RSLOp {
    public static final RSLInfixOp
        RSL_INFIX_OP_PLUS = new RSLInfixOp("+");
    public static final RSLInfixOp
        RSL_INFIX_OP_EQUALS = new RSLInfixOp("=");
    public static final RSLInfixOp
        RSL_INFIX_OP_STAR = new RSLInfixOp("*");
    public static final RSLInfixOp
        RSL_INFIX_OP_HAT = new RSLInfixOp("^");

    /*Private field containing text for printing RSL.*/
    private String text;

    /*Private constructor used only here for creation of
       contants.*/
    private RSLInfixOp(String text) {
        this.text = text;
    }
    ...
}
```

Example 4.7 Non–terminal which consists of several alternatives, which are non–terminals.

$$
\begin{aligned}
Statement ::= & \\
& StatementExpression \mid \\
& IfStatement \mid \\
& ReturnStatement \mid \\
& \vdots
\end{aligned}
$$

Implemented in Java in the following classes:

```
public abstract class Statement {...}
public class ExpressionStatement extends Statement {...}
public class IfStatement extends Statement {...}
public class ReturnStatement extends Statement {...}
⋮
```

Example 4.8 Non–terminal containing several non–terminals.

$$
\begin{aligned}
IfStatement ::= & \\
& Expression \mid \\
& Statement \mid \\
& Statement?
\end{aligned}
$$

Implemented in Java in the following class:

```
public class IfStatement extends Statement implements
    JavaElement {
  private Expression condition;
  private Block ifBlock;
  private Block optionalElseBlock;

  public IfStatement(Expression condition, Block ifBlock, Block
      optionalElseBlock) {
    this.condition = condition;
    this.ifBlock = ifBlock;
    this.optionalElseBlock = optionalElseBlock;
  }
  ...
}
```

Example 4.9 Non–terminal which consists of several alternatives, which are all terminals.

$$
\begin{aligned}
\mathit{Modifier} ::= & \\
& \mathit{public} \mid \\
& \mathit{private} \mid \\
& \mathit{static} \mid \\
& \mathit{abstract} \mid \\
& \vdots
\end{aligned}
$$

Implemented in Java in the following class:

```
public class Modifier implements JavaElement {
    public static final Modifier PUBLIC =
        new Modifier("public");
    public static final Modifier PRIVATE =
        new Modifier("private");
    public static final Modifier STATIC =
        new Modifier("static");
    public static final Modifier ABSTRACT =
        new Modifier("abstract");

    /*Private field containing the text which must be used
      in the writing of Java source code.
    */
    private String text;

    /*Private constructor for creating the constants*/
    private Modifier(String text) {
        this.text = text;
    }
    ...
}
```

as the RSL AST. The source code for the classes implementing the Java AST can be found in Appendix E.4.

4.2.3 Front End

The front end of the translator, i.e. the part transforming an RSL ASCII file to an RSL AST was created using the tool ANTLR. ANTLR creates a lexer and a parser based on a grammar file. The specification of the grammar can be found in Appendix D.1.

The grammar file contains the specifications of both the lexer and the parser. The specification of the lexer and parser are placed in two sections in the file. The file starts by stating a few general options, namely which packages should be imported in the files generated and the implementation language of the lexer and parser. The *translator.rsllib* is imported because it is used in the generation of the RSL AST. The implementation language is of course set to Java.

The specification of the lexer starts by setting a number of options. One of these options is the number of characters of lookahead the lexer should use. This option is set to 2 by the statement `k=2;`, to be able to differentiate between the following "*_" where _ represents any character and "*/" which ends a comment section among other things. The lexer allows only the ASCII set of characters, since it is the ASCII representation of RSL that is parsed by setting the option `charVocabulary='\u0000'..'\u007F';`

By default, ANTLR matches each token against a literal table and changes the token type accordingly. This is turned of by setting the option `testLiterals=false;`. This is done to ensure that keywords can be used as part of an identifier. If this was not done, the name `my_hd` could not be used, because the `hd` part would be recognized as the **hd** operator. The option is turned on for the rules recognizing identifiers which can then be changed to other tokens. Comments and white space are ignored by setting the option `$setType(Token.SKIP);` for the two rules matching comments and white space.

The parser section of the grammar also uses a lookahead of two to be able to differentiate between alternatives of a rule having a common prefix. An example of this is the rule `type_def` which has three alternatives; `sort_def`, `variant_def`, and `short_record_def`. All of the rules for matching the three alternatives start with an `IDENT`, therefore a lookahead of two is needed to distinguish between them.

The solution for ensuring different precedence levels between operators are solved, as usual, in a top down parser. To ensure that * are evaluated before +, there are two rules for the operators at these levels. `infix_expr_pr5` matches either an infix expression using an `infix_operator_pr5` or an `infix_expr_pr4`

expression. `infix_expr_pr4` matches either an infix expression using an `infix_operator_pr4` or an `infix_expr_pr3`. The two operators + and * are matched by `infix_operator_pr4` and `infix_operator_pr5` respectively. The rules are shown in Example 4.10.

The action code of the parser generates an instance of RSLAst if parsing is successful. The lexer and parser generated is used by instantiating the lexer with a *FileReader* of the file to parse as argument, and use the lexer as argument to the constructor of the parser. To obtain the result of the parsing, a method in the parser is called. The method corresponds to the starting rule of the grammar. The use of the lexer and parser is listed in Example 4.11.

4.2.4 Translation Module

The translation module in the first version of the translator was implemented by hand. It is implemented in the class *translator.Translator*. The functionality is implemented as a number of static methods. There is one top level function which takes an RSLAst as parameter and returns a JavaAst. This top level function uses other functions for generating parts of the JavaAst.

The RSLAst provided as argument to the method is not type decorated. The type decoration of the RSLAst is initialized by the translation module. The reason for this is that a specification may contain an *extending class expression*, where the *base class* may be a *scheme instantiation*. A scheme instantiation is a reference to a scheme, which is defined in another place, normally in another file. In this case, the translator must start by translating the class of the scheme instantiation, because it may contain types and values, which are used in the extending class. Before the translator is able to parse the class expression of the scheme instantiation, it must be decorated, and therefore the initialization of the type decoration is placed in the translation module. The type decoration is done by first letting a *ParentVisitor* traverse the RSLAst and then let a *TypeDecorateVisitor* traverse the RSLAst. The idea of the visitors was presented in Section 3.2.3. The source code for the visitors can be found in Appendix E.5.

The creation of the JavaAst is done by the top–level method which creates an instance of a JavaAst and returns it. The contents of the JavaAst are results of invocations of other methods, as shown in Example 4.12.

Many of the constructs in an RSLAst contain a list of some constructs, which must be handled individually. This is done by using recursion in the following way. One method checks, using an if statement, whether the list is empty or not, and if the list is empty, then the recursion stops. In case the list is not empty, then the method invokes a second method on the head

Example 4.10 Rules for different precedence levels of operators.

```
infix_expr_pr5 returns [ValueExpr ve] {
    ve = null;
    ValueExpr ve1 = null;
    RSLInfixOp rio = null;
    ValueExpr ve2 = null;
    ValueExpr ve3 = null;
}
    :   ve1 = infix_expr_pr4
        (
            rio = infix_op_pr5 ve2 = infix_expr_pr4
                {ve3 = ve1; ve1 = new ValueInfixExpr(ve3, rio, ve2);}
        )*
        {ve = ve1;}
    ;

infix_expr_pr4 returns [ValueExpr ve] {
    ve =  null;
    ValueExpr ve1 = null;
    RSLInfixOp rio = null;
    ValueExpr ve2 = null;
    ValueExpr ve3 = null;
}
    :   ve1 = disamb_expr
        (
            rio = infix_op_pr4 ve2 = disamb_expr
                {ve3 = ve1; ve1 = new ValueInfixExpr(ve3, rio, ve2);}
        )*
        {ve = ve1;}
    ;

infix_op_pr5 returns [RSLInfixOp rio] {rio = null;}
    :   PLUS {rio = RSLInfixOp.RSL_INFIX_OP_PLUS;}
    |   HAT {rio = RSLInfixOp.RSL_INFIX_OP_HAT;}
    ;

infix_op_pr4 returns [RSLInfixOp rio] {rio = null;}
    :   STAR {rio = RSLInfixOp.RSL_INFIX_OP_STAR;}
    ;
```

Example 4.11 Front end of the first version.

```
RSLLexer lexer = new RSLLexer(fr);
RSLParser parser = new RSLParser(lexer);
RSLAst rslast = parser.rslast();
```

Example 4.12 Top level function of translation module.

```
public static JavaAst rslast2javaast(RSLAst rslast) {
    JavaAst _v0 = null;

    RSLMap < String, CompilationUnit > compilationUnitMap =
        rslast2javaast(
            rslast.getLibModule().getSchemeDef().getClassExpr(),
            rslast
        );

    _v0 = new JavaAst(compilationUnitMap);

    return _v0;
}
```

of the list and invokes itself on the tail of the list. This way of recursively running through the elements of a list is also used in a slightly more complex way. The recursion may be combined with a check of whether the head fulfils some condition or not. Only if the condition is met, the second method is invoked. An example of this is shown in Example 4.13 where the method makeClassDeclarationList1 checks, whether a list of declarations is empty or not. If the list of declarations is empty, it returns an empty list, else it checks if the head of the list is a type declaration. If it is a type declaration, then it invokes the method makeClassDeclaration2 on the head of the list before it invokes itself on the tail of the list.

In the first version of the translation module, a number of features may be controlled during translation. These features include, among other things, whether or not the classes generated in the translation of type definitions should implement the visitor design pattern, and in case the design pattern is implemented then the name of the visitor. The method makeVisitorMethod is invoked by the methods translating type definitions. The makeVisitorMethod either returns an empty list of methods or a list containing an accept method for the class. The name of the visitor is retrieved from a property file by the statement translator.getProperty("visitor");. The method is shown in Example 4.14. A description of the properties which may be controlled in the translation can be found in Appendix A.

Example 4.13 Use of recursion in the translation module.

```
public static RSLList < ClassDeclaration >
    makeClassDeclarationList1(RSLList < Decl > dl) {
    RSLList < ClassDeclaration > _v0 = null;
    if (dl.equals(new RSLListDefault < Decl > ())) {
        RSLList < ClassDeclaration > _v1 = null;
        _v1 = new RSLListDefault < ClassDeclaration > ();
        _v0 = _v1;
    }
    else {
        if (dl.hd() instanceof TypeDecl) {
            RSLList < TypeDef > tdl = ( (TypeDecl) dl.hd()).
                getTypeDefList();
            RSLList < ClassDeclaration > _v1 = null;
            _v1 = makeClassDeclarationList2(tdl).concat(
                      makeClassDeclarationList1(dl.tl()));
            _v0 = _v1;
        }
        else {
            RSLList < ClassDeclaration > _v1 = null;
            _v1 = makeClassDeclarationList1(dl.tl());
            _v0 = _v1;
        }
    }
    return _v0;
}
```

Example 4.14 *makeVisitorMethod* method.

```
public static RSLList < MethodDeclaration >
    makeVisitorMethod(Id id, boolean abstractMethod) {
  RSLList < MethodDeclaration > _v0 = null;
  if (createVisitorMethods) {
    if (abstractMethod) {
      _v0 = ...
    }
    else {
      _v0 = new RSLListDefault < MethodDeclaration > (
          new MethodDeclaration(
            new RSLListDefault < Modifier > (Modifier.PUBLIC),
            new SimpleName("accept"),
            PrimitiveType.JAVA_VOID,
            new RSLListDefault < SingleVariableDeclaration >
              (new SingleVariableDeclaration(
                    new RSLListDefault < Modifier > (),
                    new ReferenceType(
                        (translator.getProperty("visitor") !=
                            null ?
                          new SimpleName(
                              translator.getProperty("visitor"
                                  )) :
                          new SimpleName("TYPE_UNKNOWN")),
                              null),
                    new SimpleName("visitor"),
                    null)),
            new Block(new RSLListDefault < Statement >
                      (new ExpressionStatement(
                           new MethodInvocation(
                               new SimpleName("visitor"),
                               makeVisitName(id),
                               new RSLListDefault < Expression
                                   >
                               (new ThisExpression(null))))))
          )
        );
    }
  }
  else {
    _v0 = new RSLListDefault < MethodDeclaration > ();
  }
  return _v0;
}
```

In Chapter 2, the exact translations of the different constructs in RSL were treated. The general idea of the translation of a basic class expression is that it should result in a number of classes, according to the discussion in Section 2.3.3. Each class should be placed within its own *CompilationUnit*. Each *CompilationUnit* represents a file in the output of the translator. The basic class expression results in one class named after the scheme containing the basic class expression. This class contains methods corresponding to the functions in the basic class expression. The type definitions in the basic class expression result in a number of classes named after the type definitions, according to the translations in Section 2.3.3. If the basic class expression contains test cases, a main method is generated with a System.out.println statement for each test case.

These three issues are handled by three different methods in the translation module. The result of the methods are placed in three different places in the resulting JavaAst.

The translation of functions in a basic class expression is handled by a method makeMethodDeclarationList1, which runs recursively through the list of declarations given as parameter and builds a list of method declarations in Java. makeMethodDeclarationList1 uses the scheme of recursion presented above, checking the list of declarations for value declarations. For each value declaration, it invokes makeMethodDeclarationList2. makeMethodDeclarationList2 uses the same scheme of recursion checking the value definitions for explicit function definitions. For each explicit function definition, it invokes makeMethodDeclaration. makeMethodDeclaration creates a method declaration and returns it to makeMethodDeclarationList2, which wraps the method declaration in a list and concatenates the list to the result. The block of the method declaration is created by another function makeBlock, which is invoked with the value expression of the explicit function definition as argument. The idea of the method makeBlock was presented in Section 2.4.3. The result of makeMethodDeclarationList1 is a list of method declarations, which can be used as a parameter in the creation of a class in Java corresponding to the scheme being translated.

A basic class expression may contain test cases. The test cases result in a main method in the class created. This is done by a method makeMainMethodDeclaration and a number of auxiliary methods, which run through the list of declarations in the basic class expression looking for test case declarations and test cases inside of them. The methods use the same scheme of recursion as makeMethodDeclarationList1. If a test case declaration and a test case definition is found, makeMainMethodDeclaration returns a list of methods containing one method main, else the method returns an empty list of methods. The list of methods returned by makeMainMethodDeclaration

is concatenated with the list created by makeMethodDeclarationList1.

Type declarations in a basic class expression is handled by a third method makeClassDeclaration1, which, like the methods described above, runs through the list of declarations. For each kind of type definition translated there is an auxiliary method for creating the corresponding classes. The methods inside the classes generated are created by other auxiliary methods. These auxiliary methods run through the content of the type definitions and creates the equals and the toString methods needed according to the translation defined in Chapter 2. The result of makeClassDeclaration1 is a list of *ClassDeclaration*'s.

In the top level method rslast2javaast each class declaration is wrapped in a *CompilationUnit* and the result is joined with a *CompilationUnit* created from the translation of value declarations and test case declarations.

The idea of the methods for translating value expressions is given in Section 2.4.3, which describes three methods for carrying out the translation. In the actual implementation, there are more methods, but the idea remains the same. The difference is that instead of having three large methods: One for creating blocks, one for creating statements, and one for creating expressions, each of these is split into a number of overloaded methods, which handles one kind of value expressions each. The difference is illustrated in Example 4.15.

The methods involved in the translation of value expressions contain, among others, these two parameters VariableDeclarationStatement vds and **int** currentVariableNumber. The purpose of these two parameters are to perform the translation as illustrated in Example 2.34 namely to introduce a new variable for each block entered, assigning the result to the variable, and at the end of the block, assign the new variable to the variable of the enclosing block. The parameter vds holds the variable to which the result of the block must be assigned, and the parameter currentVariableNumber holds the number with which the variable may be named to avoid name clashes with the variables of the enclosing blocks. For each nested level currentVariableNumber is incremented. The variables are named "_v0" at the first level and "_v1" at the second level and so on. The method makeBlock takes a third parameter, which is a boolean value stating whether the last statement should be a return statement instead of an assignment. The source code for the translation module can be found in Appendix E.1.1.

4.2.5 Back End

The back end of the first version of the translator was implemented by hand as a visitor, *StringJavaVisitor*, which simply traverses a JavaAst and writes the corresponding Java source code. The visitor design pattern implemented

Example 4.15 Illustration of difference between implementation and idea presented in section 2.4.3.

```
public static RSLList < Statement >
    makeStatementList(IfExpr ifExpr,
                      VariableDeclarationStatement vds,
                      int currentVariableNumber) {
    ...
}

public static RSLList < Statement >
    makeStatementList(CaseExpr caseExpr,
                      VariableDeclarationStatement vds,
                      int currentVariableNumber) {
    ...
}

...

Instead of

public static RSLList < Statement >
    makeStatementList(ValueExpr valueExpr,
                      VariableDeclarationStatement vds,
                      int currentVariableNumber) {
    if(valueExpr instanceof IfExpr)
        ...
    else if(valueExpr instanceof CaseExpr)
        ...
    ...
}
```

by the JavaAst is the variant with the traversal of the object structure placed in the visitor, this makes it is very to generate the Java source code. It is easy to control where the code of the subparts of a construct should be written.

One example of this is the if statement, which is shown in Example 4.16. The visitor starts by writing the **if** keyword, then it invokes the accept method of the condition with itself as argument for writing the condition. After the condition has been written it invokes the accept method of the if–block for writing this part. Then it checks if there is an optional else block, and if so invokes the accept method of the else–block.

Example 4.16 Visit method for if–else statement.

```
public void visitIfStatement(IfStatement ifStatement) {
    result.append("if(");
    ifStatement.getCondition().accept(this);
    result.append(")\n");
    ifStatement.getIfBlock().accept(this);
    result.append("\n");
    if (ifStatement.getOptionalElseBlock() != null) {
        result.append("else");
        ifStatement.getOptionalElseBlock().accept(this);
        result.append("\n");
    }
}
```

Two properties control whether or not to write the generated Java source code to files or to print them to *stdout*. In case the Java source code is written a property controls to what directory the files are written. The description of the properties can be found in Appendix A. The source code for the *StringJavaVisitor* can be found in Appendix E.5.7.

4.2.6 Control Module

The control module in the first version of the translator is very simple. It is implemented as a main method within the *Translator* class. The source code for the control module may be found in Appendix E.1.1 line 2235. The purpose of this module consists of two parts. The first purpose is to be user interface of the translator. It is the control module which must be executed by a user on a command–line. The second purpose is to initiate and control the translation. The translation process is, as shown in Figure 3.20 on page 89 and summarized below. The names in the summary correspond to the names of the figure.

1. A filestream of the file containing the specification is passed on to the front end, *RSLLexer* and *RSLParser*.

2. The result of the front end is an RSLAst which is stored in a variable.

3. The RSLAst is passed on as argument to the translation module, *Translator*.

4. The result of the translation module is a JavaAst which is stored in a variable.

5. The JavaAst is traversed by a visitor creating Java source code, *StringJavaVisitor*.

4.3 Second Version of the Translator

The second version of the translator is implemented in a different way than the first version, due to the bootstrapping process. The front end and the back end of the second version of the translator are implemented in Java like the first version, and they are actually very similar to the first version. The differences lies within the translation module and the data structures, which in the second version were specified in RSL and translated using the first version.

In Section 3.3, two versions of the translator were mentioned, a first version implemented entirely by hand and a second version, where the translation module was specified in RSL_0 and then translated using the first version. The specification of the translation module should handle the slightly larger subset of RSL, RSL_1. In the implementation process, however, there was an intermediate step. First, a translation module handling RSL_0 was specified and translated into a new executable version of the translator. Afterwards, the specification was extended to handle the slightly larger subset RSL_1, and made executable by the steps described in Section 3.3. This intermediate step is mainly for testing purposes. The specified version of the translation module in the intermediate step should produce the same result as the version implemented by hand.

4.3.1 AST Representation of RSL

In the second version of the translator the RSL AST was defined as a specification in RSL and translated using the first version of the translator. To avoid any confusion on the *classpath* between the two versions, all types in

the second version were prefixed with `"TM_"`. The second version is a little different from the first, because the first version uses constants for representation of terminal symbols, whereas the second version uses classes for representation of all symbols. The reason for this is that a non–terminal with only terminal symbols on the right–hand side is specified as a variant definition with alternatives only consisting of constants. The translation of such a variant definition is, as described in Chapter 2, an abstract class with an empty class extending the abstract class for each alternative of the variant definition. An example of this difference is shown in Example 4.17 where the implementation and specification of the rule for an infix operator in RSL is listed.

4.3.2 AST Representation of Java

The Java AST was specified in RSL in the second version of the translator. As with the RSL AST, all types were prefixed with `"TM_"` to avoid confusion on the *classpath* between the different versions. The Java AST was also changed, like for the RSL AST. Non–terminals containing only terminal symbols are also implemented as a variant definition resulting in the use of classes rather than constants in the Java translated.

4.3.3 Front End

The front end of the second version of translator is very similar to the first version. The second version is also implemented using ANTLR, i.e. it is a grammar file, from which ANTLR generates a lexer and a parser. The grammar file of the second version can be found in Appendix D.2. The rules of the second version are very similar to the rules of the first version. There are two differences between the two versions. The second version must recognize RSL_1 rather than RSL_0. Furthermore, the data structure has changed between the two versions. This means that the action code of the grammar has changed. The second version of the front end must generate an RSL AST corresponding to the one required by the second version of the translation module as described in Section 4.3.1.

4.3.4 Translation Module

Even though the translation module in the second version was specified in RSL and translated using the first version of the translator. The principles of the translation between the two AST representation of the languages remain the same. An overview of the specification is given in Chapter 5. All the

Example 4.17 Difference in implementation and specification of prefix operators in RSL.

$$\begin{aligned} prefix\_op ::= \\ & hd \mid \\ & tl \end{aligned}$$

Implementation in Java, First version:

```
public class RSLPrefixOp extends RSLOp {
    public static final RSLPrefixOp RSL_PREFIX_OP_HD =
        new RSLPrefixOp("hd");
    public static final RSLPrefixOp RSL_PREFIX_OP_TL =
        new RSLPrefixOp("tl");

    /*Private field containing text needed for printing RSL.*/
    private String text;

    /*Private constructor used only in creation of constans.*/
    private RSLPrefixOp(String text) {
        this.text = text;
    }
    ...
}
```

Specification in RSL, Second version:

TM_PrefixOperator == TM_RSL_HD | TM_RSL_TL

Translated into Java:

```
public abstract class TM_PrefixOperator {...}

public class TM_RSL_HD extends TM_PrefixOperator {...}

public class TM_RSL_TL extends TM_PrefixOperator {...}
```

properties, which in the first version were controlled by a property file, are in the second version changed to parameters to the modules. The reason for this is that the use of property files cannot be specified in the subset of RSL used for the specification. The properties are still kept in a property file in the second version of the translator. The access to the property file is moved to the control module, which reads the properties and passes them on to the other modules as parameters.

The type decoration of the RSL AST is in the second version also implemented as a visitor. The principle of the visitor is the same as in the first version, but the different data structures makes it a little different. One of the differences lies in the fact that the visitor at some points needs to go through a wrapper construct to get to the actual construct. An example of this is an enumerated list expression. To be able to use an enumerated list expression as a type of its own in RSL, it is specified as a short record definition in the data structure. A list expression is implemented as a variant definition with the different possible list constructs as alternatives. The alternative for an enumerated list expression is a record constructor `Make_TM_Enumerated_List_Expr` which contains a `TM_Enumerated_List_Expr` as a component. The type decorate visitor must go through the class `Make_TM_Enumerated_List_Expr` to get to the actual enumerated list expression.

In the construction of the AST representation of Java, there are a lot of similarities between the two versions of the translator. The first version of the translation module was written using recursion and static methods in Java, which corresponds to the Java source code generated, when using explicit function definitions and recursion in RSL in a scheme not instantiated by objects. Many of the functions in the specification of the second version correspond to methods in the implementation of the first version. Three of the main methods described for the first version can actually be found as functions in the specification.

1. The method makeMethodDeclarationList1 in the first version is in the second version the function `makeMethodDeclarationList1`.

2. The method makeMainMethodDeclaration in the first version is in the second version the function `makeMainMethodDeclaration`.

3. The method makeClassDeclarationList1 in the first version is in the second version the function `makeCompilationUnitList1`.

The signatures of the methods and functions are actually identical for the first two items listed. makeMethodDeclarationList1 as method takes a list of

declarations and returns a list of method declarations, this is also the case for the function in the second version. makeMainMethodDeclaration as a method takes a list of declarations and returns a list of method declarations. The same is the case for the function `makeMainMethodDeclaration` in the second version. The method makeClassDeclarationList1 is the only one which has changed. The first change is that the method in the first version only takes a list of declarations as parameter, whereas the function in the second version takes four more parameters, three of the parameters are used to create compilation units rather than classes. These three parameters hold the package declaration, the import statement list, and an optional id if the class must extend another class, which is needed to create a compilation unit. The fourth extra parameter is used to determine, whether the classes created should implement the visitor design pattern, which in the first version was controlled by a property. The idea of the method `makeClassDeclarationList1` and the function `makeCompilationUnitList1` are the same namely to create the classes which make up the translation of the type definitions in a basic class expression.

These correspondences between methods in the implementation of the first version and functions specified in the second version can be found many times in the two versions of the translation module. There may be some variations between the number of parameters for the methods and the functions, but this is mainly due to the fact that the properties must be passed around between the functions, until they are used in some function in the hierarchy of function calls. An example of this is the `TM_Optional_Id, visitorId`, which is a parameter to the top–level function `rslast2javaast`. This parameter indicates whether or not the classes created in the translation of type definitions should implement the visitor design pattern, and if the visitor design pattern is implemented, then the name of the visitor is the `TM_Id` of the `TM_Optional_Id`. The parameter `TM_Optional_Id, visitorId` is part of the functions listed below, which eventually calls the function `makeVisitorMethod` that uses the parameter.

1. `rslAst2JavaAst`
2. `rslAst2CompilationUnitList`
3. `makeCompilationUnitList1`
4. `makeCompilationUnitList2`
5. `makeClassDeclarationList1` which checks whether the method `makeVisitorMethod` should be applied or not, by checking whether `visitorId` is a `Make_TM_Id` or not.

6. `makeVisitorMethod` creates a method based on the `TM_Id` in the `visitorId` .

Another difference between the two versions of the translator is the data structures used in the two versions. The two versions of the data structures are described previously in this chapter and the differences between them have some influence on how the translation module works. An example of the difference is shown in Example 4.18. The Java AST in the second version requires the translation module to wrap the value literal after creation.

Example 4.18 Differences in creation of an if statement between the first and second version of the translator.

Creation of a value literal in the first version:

```
public static Expression makeExpression(ValueExpr valueExpr) {
  Expression _v1 = null;
  ...
  else if (valueExpr instanceof ValueLiteral) {
    Expression _v2 = null;
    ...
    else if (valueExpr instanceof ValueLiteralInteger) {
      ValueLiteralInteger vli = (ValueLiteralInteger)
          valueExpr;
      _v2 = new IntegerLiteral(vli.getText());
    }
    ...
  }
}
```

Creation of a value literal in the second version:

```
makeExpression(ve) ≡
case ve of
  Make_TM_ValueLiteral(vl) →
    case vl of
      TM_ValueLiteralInteger(t) →
        Make_TM_JavaValueLiteral(
          Make_TM_JavaValueLiteralInteger(
            mk_TM_JavaValueLiteralInteger(t))),
```

.

4.3.5 Back End

The back end of the second version of the translator is very similar to the first version. The back end is implemented as a visitor traversing the Java AST and writing the corresponding Java source code. The major difference between the first and the second version of the back end is the differences between the two data structures. The principle of the back end is exactly the same in the two versions.

In the second version of the back end, the use of properties in the translation was moved to the control module. The reason for this was to let only one module be responsible for handling a property file.

4.3.6 Control Module

The control module is a little larger in the second version compared to the first version. In the first version, the control module was implemented as a main method inside the translation module, whereas in the second version it is placed in a separate class. The control module uses file access, which cannot be specified in the subsets of RSL translated. Therefore, it cannot be part of the modules which are specified, hence, it cannot be part of the translation module.

In the second version, the control module is the only module which accesses a property file. The properties are passed on as parameters to the other modules. The principle of the control module is exactly the same as in the first version: it serves as interface for the users and it is responsible for initialization of the other modules. The translation is started by calling the front end and passing on a file stream of the file containing the specification. The result of the front end is stored in a variable and passed on to the translation module. The result of the translation module is stored in another variable and then traversed by the visitor of the back end for generating the output of the second version of the translator. The source code of the control module of the second version can be found in Appendix F.1.1.

Chapter 5

Overview of the Formal Specification

This chapter gives an overview of the formal specification of the translator. The translation module is, as stated in Chapter 3, developed using a bootstrapping process. The bootstrapping process means that the specification of the translation module are defined in a number of versions.

In the overview of the development process given in Section 3.3 it was stated that there are two versions of the translator. One which was implemented by hand, capable translating the subset of RSL, named RSL_0, and a second version of the translator, which was specified in RSL_0 and translated using the first version of the translator. The second version of the translator should then be able to translate the slightly greater subset of RSL named RSL_1.

As stated, in Section 4.3 there are two version of the translator which are specified in RSL:

1. An intermediate version between the first and the second version.

2. The second version.

The intermediate version was specified in RSL_0 and is able to translate RSL_0. This intermediate version was used for translating the second version of the translator.

To avoid confusion between the two versions of the specification, a list of the modules is given here.

First version of the specification:

1. RSLAst_Module

2. JavaAst_Module
3. RSLAst_WrapperModule
4. RSLAst_WrapperModule_2
5. Translation_Module

Second version of the specification:

1. RSLAst_Module2
2. JavaAst_Module2
3. RSLAst_WrapperModule2
4. RSLAst_WrapperModule_22
5. Translation_Module2

The schemes listed above are described in the following sections. All the specifications are specified using the subset of RSL named RSL_0.

5.1 Abstract Syntax Tree for RSL

The specification of the abstract syntax tree is based on the definition of the syntax, which may be found in [11] with the addition of *test cases* added by the people at UNU/IIST [1]. The specification only defines the types necessary to build an abstract syntax tree of a specification in RSL. There are no values defined in this module.

The specification is developed using a few simple ideas. The ideas are based on the structure of the right–hand side of a non–terminal in the grammar. The ideas presented in the following correpond to the ideas used in the implementation of the first version of the translator.

A non–terminal of the following form:

$$\begin{aligned} NT &::= NT_1 \mid \ldots \mid NT_n \\ NT_1 &::= NT_{i_1} \ldots NT_{j_1} \\ &\vdots \\ NT_n &::= NT_{i_n} \ldots NT_{j_n} \end{aligned}$$

is specified using the following constructs:

NT == Make_NT$_1$(nt$_1$: NT$_1$) |
⋮ |
Make_NT$_n$(nt$_n$: NT$_n$),
NT$_1$ :: nt$_{i_1}$: NT$_{i_1}$ ... nt$_{j_1}$: NT$_{j_1}$,
⋮
NT$_1$ :: nt$_{i_n}$: NT$_{i_n}$ ... nt$_{j_n}$: NT$_{j_n}$

An example of this is the TM_ValueExpr and the TM_VariableOrValueName which is shown in Example 5.1

Example 5.1 Implementation of TM_ValueExpr and TM_VariableOrValueName

value_expr ::=
⋮
value_or_variable_name
⋮
value_or_variable_name ::=*id*

Specification:

TM_ValueExpr == Make_TM_ValueOrVariableName(
value_or_variable_name : TM_VariableOrValueName),
TM_VariableOrValueName :: id : TM_Id

Non–terminals with several alternatives, which all are terminal symbols, are specified as variant definitions with only constants.

$$NT ::= T_1 \mid T_2 \mid \ldots \mid T_n$$

is specified as follows:

NT == T$_1$ | T$_2$ | ... | T$_n$

An example of the second type of rule is the rule for prefix operators in RSL. The syntax rule for the prefix operator and the corresponding specification are shown in Example 5.2.

Example 5.2 Rule: *prefix_op* RSL: TM_PrefixOperator.

$$
\begin{aligned}
prefix\_op ::= & \\
& hd \mid \\
& tl
\end{aligned}
$$

TM_PrefixOperator == TM_RSL_HD | TM_RSL_TL

The ideas presented above are not followed at all times. Some grammar rules, which present a hierachy, are simplified by moving constructs up in the hierachy. An example of this is some of the rules for value expressions – the principle is shown in Example 5.3.

5.2 Abstract Syntax Tree for Java

There are several ways to represent Java in an abstract way according to the literature. The way it is represented in this module is combination of the best parts of two representation found in [13] and [5]. The main reason for this combination is a lack of literature dealing with the new version of Java, 1.5, which at the start of this project was going through beta–testing. The top–level structure is TM_JavaAst which consist of a TM_CompilationUnit–list. The elements of TM_CompilationUnit–list represent the files, which is the output of the translation. The idea in the specification is the same as described in the previous section for the AST representation of RSL.

5.3 Wrapper Modules

Two wrapper modules are specified. The purpose of the two modules is to specify some additional types and functions in RSL, which can be used in the *Translation_Module*.

The first module *RSLAst_WrapperModule* and *RSLAst_WrapperModule2* defines a number of types, which are not part of the AST representation of RSL, but which are used for decorating the RSL AST after it has been parsed. The specification contains one variant definition, which holds a number of record constructors, which represent the different types a node can have in the decorated RSL AST.

The second module *RSLAst_WrapperModule_2* and *RSLAst_WrapperModule_22*

Example 5.3 Simplifying a hierachy.

value_expr ::=
    ...
    structured_expr |
    ...

structured_expr ::=
    ...
    case_expr |
    ...

case_expr ::=
    value_expr
    case_branch-list

Translation according to the rules:

```
TM_ValueExpr == ... |
        Make_TM_StructuredExpr(
            structured_expr : TM_StructuredExpr) |
        ⋮

TM_StructuredExpr == ... |
        Make_TM_CaseExpr(case_expr : TM_CaseExpr) |
        ⋮

TM_CaseExpr :: value_expr : TM_ValueExpr
               case_branch_list : TM_Case_Branch*
```

Simplied to:

```
TM_ValueExpr ==
   TM_CaseExpr(value_expr : TM_ValueExpr,
               case_branch_list : TM_Case_Branch*)
```

defines a number of functions in RSL. The idea is to allow use of these functions in the translation module, therefore the translation module extends this module. The idea of *RSLAST_WrapperModule_2* is that it is never translated into Java. The functions, which are specified in the module, are implemented in Java elsewhere in the system. The reason for doing this is to allow for interaction between the parts of a system, which are specified in RSL and translated, and the parts which are implemented in Java. The signature between the functions defined in *RSL_WrapperModule_2* and the methods implemented in Java must be identical.

5.4 Translation Module

The translation module of the translator is specified in a module called *Translator_Module* and *Translator_Module2*. The purpose of the translation module is to do the translation between an RSL AST and a Java AST.

This translation is done by a function named `rslAst2javaAst`. The function has the following signature:

rslAst2JavaAst :
TM_RSLAst × TM_OptionalPackageDeclaration ×
TM_ImportDeclaration* ×
TM_OptionalSimpleName ×
TM_OptionalId × **Text*** × **Bool**
→ TM_JavaAst
rslAst2JavaAst(ra, opd, idl, ext, visitorId,
ignoreList, writeExtensionFiles) ≡ ...

`ra` is the abstract representation of RSL which must be translated.
`opd` is contains either a package declaration or nothing determining to which package the generated classes should belong.
`idl` is a list of packages the generated classes must import.
`ext` is a optional identifier of a Java class if all the generated class must extend a common super class.
`visitorId` is an optional identifier of a visitor class in Java if the generated classes must implement the visitor design pattern.
`ignoreList` is a list of schemes which should be parsed but never translated. To ensure the wrapper module functionality described in the previous section.
`writeExtensionFiles` is a boolean value determining, whether the code generated from translating basic class expression of an extending class expression should be written or not.

The function creates a `TM_JavaAst` using the `mk_TM_JavaAst` function defined in by the short record definition `TM_JavaAst` in the *JavaAst_Module*, the parameters to the function are applications of other functions defined in the translation module. Each of them takes care of one part of the translation. The ideas of the top–level functions have already been presented in Section 4.3.4.

The type decoration must be initialized by the translation module, according to the discussion in Section 4.3.4. This means that the translation module must be able to create an instance of the *TM_TypeDecorateRSLAstVisitor* class and invoke the accept method in *TM_RSLAst* with the visitor as parameter. *TM_TypeDecorateRSLAstVisitor* is the second version of the type decorate visitor. The source code for the visitor can be found in Appendix F.2.7. The translation module does not have any knowledge about *TM_TypeDecorateRSLAstVisitor* and nor does it have any knowledge about an accept method, but the specification should still be type checked using the existing type checker. The solution for this consists of two parts. The actual initialization of the type decoration has been moved to an auxiliary function, `Runner_instance_typeDecorate`. The function is specified in the *RSLAst_WrapperModule_2*, and is therefore never translated, but must be specified elsewhere in the system. To be able to call the method in the translation of the translation module, the method must be placed within the class created. This is achieved by a property used in the translation process, which allows for insertion of Java source code at the end of the class created in the translation of a scheme in RSL. By using these properties and features implemented it is possible for a module specified in RSL to interact with parts of a system implemented in Java. It should be noted that these features are not limited to be used in the translation of the translation module, but can also be used when applying the translator in other projects.

Chapter 6

Test

The tool implemented in this project involves a number of different packages, which have been developed using different tools and languages as described in previously. Therefore, testing the tool has been a little different from the usual test in a software development project.

6.1 Purpose

The purpose of testing is to increase the confidence in the correctness of the tool developed. It cannot be proven through tests that there are no errors in the implementation, but tests can make it plausible that the implementation works correctly.

6.2 Test Schemes

All parts of the different versions of the translator have been tested. To what degree and how the testing have been done vary between the different parts of the translator.

The main part of the testing has been done as black box testing, which tests that the functionality of the translator is as expected [18]. The functionality has been tested by translating numerous examples of small specifications, and controlling that the generated Java source code complied to what was expected according to the translations defined in Chapter 2. The translation module was as stated in Chapter 5, specified in an intermediate version capable of translating RSL_0, and then in a second version capable of translating RSL_1. This result in the following translations and test phases:

1. Implementation of the first version by hand.

2. Testing of the first version using numerous examples.
3. Translation of the intermediate version of the translation module specified in RSL_0 using the first version.
4. Testing of the executable version of the intermediate version using numerous examples.
5. Translation of the second version of the translation module specified in RSL_0 using the executable version of the intermediate version.
6. Testing of the second version using numerous examples.

The steps mentioned in the list above, namely that each version was tested separately, and that the last two versions were translated using the previous version and worked as expected, are good indications that the translator works as expected.

A selection of the examples used for testing are listed below. For each example it is described which part of the translation it tests. The specification of the examples as well as the source code generated can be found in Appendix I.

LISTSUM Tests the translation of: Explicit function definitions, use of list operators, if–then–else expressions and arithmetic operators.

LIST Tests the translation of: Variant definitions using constants and record constructors and case expressions.

APPLICATION Tests the translation of: Short record definitions, application expressions and destructors.

The front end and the back end of the translator have been tested separately. The front end has been tested by using small specifications and writing the generated RSL AST to a file. The generated RSL AST was compared with what was expected according to the rules of the syntax of RSL. The back end has been tested by letting it write Java code from examples of Java AST's and controlling that the results were as expected.

The library classes in the *rsllib* package have been tested using structural testing or white box testing [18]. A test class has been written for each the library classes. Each of the test classes tries every method in a library class and writes the output to *stdout*. The results were then compared to the expected output. This kind of tests could has been done using a test framework like JUnit [2]. This have not been done because of the relative small size and number of library classes. The test classes for the library classes can be found in Appendix G.

6.3 Results

The results of the tests of the library classes were as expected and a print of the results can be found in Appendix H.

The results of the translation of the examples mentioned generated the Java source code as expected. They were all able to be compiled with *javacc*, and those examples which included test case declarations also gave the expected output when executed. The results can be found in Appendix I.

Chapter 7

Extensions and Further Work

This chapter provides suggestions for how to apply and expand the developments of this work. In Section 7.1 it is proposed how the developments in this project can be applied in the development of new tools for RSL. Section 7.2 and 7.3 give proposals for how to expand the translation from RSL into Java. Section 7.4 contains suggestions for how to expand the translator developed to translate a larger subset of RSL.

7.1 Creating Tools Transforming RSL

In order to make the translator developed more reuseable, a visitor for creating RSL from an RSL AST has been developed. This visitor was both used for debugging the front end and making future development of tools manipulating RSL easier. A tool for translating between different forms of RSL, e.g. from applicative RSL to imperative RSL, can use the front end for parsing RSL, specify the transformations in RSL and translate them using the translator created in this project and use the RSL visitor for writing the translated RSL.

The developer should define the tool for transformation of RSL as an RSL specification which is shown in Figure 7.1.

The tool can be made executable by the following steps. Translate the specification to Java using the translator. The translation is shown in Figure 7.2. Combine this tool with the front end and the RSL visitor to create a tool translating between different kinds of RSL. The combination is shown in Figure 7.3.

Figure 7.1 Tool translating between two kinds of RSL AST's implemented in RSL

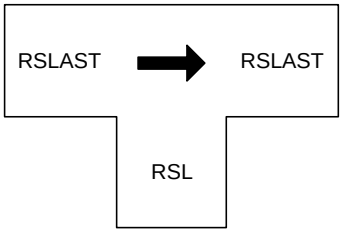


Figure 7.2 Translating the tool specified.

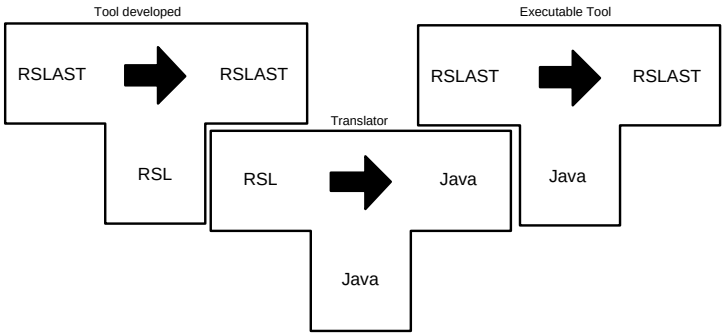

Figure 7.3 Combining the new tool developed with the front end and the RSL visitor as back end.

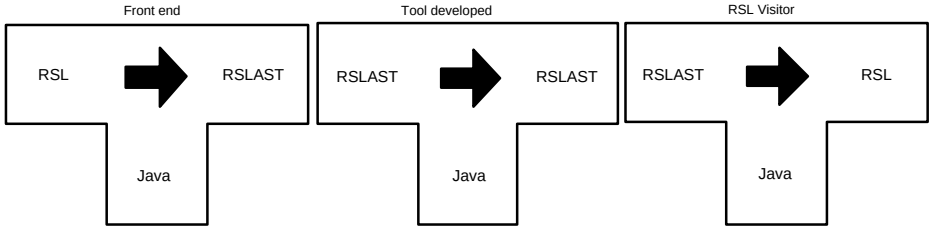

7.2 Expanding the Translation

The two subsets translated in this project RSL_0 and RSL_1 are very small subsets of RSL. To make the tool more usable the subset translated should be expanded considerable.
Possible steps of extension include:

1. Extend the set of constructs for applicative specification.
2. Add constructs for imperative specification.
3. Add possibilities for specification of communication.
4. Add possibilities for specification of parallel evaluation of expressions.
5. Add possibilities for using axioms and implicit specifications.

The first step of extension should be addition of the translations of constructs for which this project provides a translation, but which were not implemented in the tool. In addition to these the **let** expression and more patterns for the **case** expression should be added, possibly using the translations described in Section 7.3. A final addition to the first step should be the possibility of using pre–condition for functions, a suggestion for implementation of pre–conditions is shown in Section 7.3.

The second step of extension should include possibilities for specifying an imperative system. To be able to specify an imperative system, a number of additions must be made. First of all translation of variable declarations should be added. In addition to this value expressions for assignments to variables as well as value expressions for sequencing should be added. As a final addition to the second step the looping constructs **for**, **while** and **until**, which are very often used in imperative specification, should be added. Possible translations of these constructs are discussed in Section 7.3.

The third step of extension should include possibilities for specifying a system using communication. Communication in RSL is done over channels using input and output value expressions. Therefore, this step of extension must add translation of channel declarations and the value expressions for using channels, namely: input expressions and output expressions.

The fourth step of extension should include possibilities for specifying a system where several expressions may be evaluated in parallel. Parallel evaluation of expressions in RSL is done by using infix combinators. Therefore, this step of extension must include translations of a number of these. $\|$ and $[]$ are the most used infix combinators. Therefore, a translation of these must

be added. The only way processes running in parallel in RSL can communicate is by using channels. The fourth step of extension therefore depends the third step. A discussion of possible translations of the infix combinators is given in Section 7.3.

The final step of extension should include possibilities for specifying a system using axioms. This cannot not be completed entirely, because there are infinitely many ways to define a specification implicitly. The translator must add a handling of each special case of the implicit ways of specification which can be translated. However, the translator can only test for a finite number of these, and therefore this step can never be completed. Even though this step is listed as the last step the handling of some of the special cases may be introduced in any of the other steps.

7.3 Ideas for Translation of Constructs not Treated in Chapter 2

This project includes translations of a number of constructs in RSL, these were treated systematically in Chapter 2. This section contains considerations on translations of some of the constructs not included in Chapter 2. The considerations are not systematically treated, but presents ideas for a translation.

7.3.1 Variable Declarations

"RSL allows declaration of variables as known from programming language like Ada and Pascal. A variable in RSL is a container capable of holding values of a particular type." [11]. Java also allows for declaration of variables which have the same properties. Therefore, a translation of variable declarations in RSL should be as variables in Java. The use of a variable, such as assigning new values to it in RSL, corresponds to assignments in Java. Therefore, an assignment expression in RSL should be translated as an assignment expression in Java. In Java, assignment statements of variables of a reference type are just referenced to object meaning the it is possible to have many variables pointing to the same object. In RSL, on the other hand an assignment expressions assigns a copy of the value to the variable. Therefore, deep–copying of variables of reference types may be needed in Java before making assignments. Sequencing in RSL, where a number of expressions are evaluated in turn, corresponds very much to a block in Java, where a number of statements are executed in turn. For the value expressions sequenced in RSL, only the last expression may be of another type than **Unit**. This

corresponds to a return statement or an assignment statement at the end of the block, according to the use of auxiliary variables in the translator. The use of auxiliary variable was presented Section 2.4.2.

7.3.2 Channel Declarations

Commucation in RSL is specified using a concept called channels. A process may communicate values of the type specified in the **channel** declaration in both directions. In Java, there are a number of posibilities for implementing communication between systems. The possibilities for communication in Java include:

1. Streams.
2. Channels.
3. RMI.
4. CORBA.

Each of these communication concepts in Java have both advantages and disadvantages. However, it must be investigated furher, which of the possible communication schemes provides the best facilities for an implementation in Java.

The most natural choice would be to use channel in Java because they are an implementation of a CSP like channel, which corresponds very much to the channel concept of RSL. There may, however, be some issues with synchronization, because channels in Java are not synchronized in the same way that channels in RSL are. Communication in RSL is at an abstract level therefore there should be defined some ways for determining which system to communicate with and how to reach this system.

7.3.3 Parallel Composition and External Choice

The purpose of the parallel combinator $\|$ in RSL is to allow two expressions to be evaluated concurrently. The two expressions must have the type **Unit**, and it is recommended that they are state–independent. The purpose of the external choice combinator $[]$ in RSL is to specify a choice between different kinds of communication explicitly.

There are no corresponding constructs in Java for these two combinators. However, it is possible in Java to have several threads running in parallel and thereby having several expressions evaluated in parallel.

One suggestion for a translation between value expressions in parallel is to require the value expressions to be application expressions of processes in RSL. The translation of the processes in RSL could then be as classes in Java implementing the *Runnable* interface. The translation of the value expresions of the processes in RSL should be placed in the run method in the Java class. The parallel combinator expression should be kept in another class instantiating the other classes created and starting the execution.

The same solution could be used for dealing with the external choice combinator, namely only allow it to combine processes in RSL and translate them using multiple classes implementing the *Runnable* interface.

7.3.4 Pre–conditions

Explicit functions in RSL may use pre–conditions for testing that some condition is fulfilled before the function is evaluated. This is very useful to ensure that a function does not evaluate to **chaos**. The concept of ensuring that certain conditions are met before evaluating a method would be useful in Java. A pre–condition in RSL consists of a value expression which should be read–only, and it should evaluate to a boolean value. In Java exists a concept, assertions, which has many of the same properties. Assertion statements are used for controlling that an expression is true, if not an *AssertionException* is thrown. Assertion statements can be used inside a method body to check the parameters as well as the state of the program. These similarities indicate that assertions in Java may be a good translation of pre–conditions in RSL. A simple example is a pre–condition ensuring that a function using division does not divide by zero, the example and the translation is shown in Example 7.1.

Example 7.1 Translation of a function using a pre–condition.

```
value
  partial_fraction : Real ~→ Real
  partial_fration(x) ≡ 1.0/x
  pre x ≠ 0.0
```

```
public static double partial_fraction(double x) {
    assert x != 0.0;
    return 1.0/x;
}
```

7.3.5 Let Expressions

A **let** expression in RSL consists of a number of declarations of values and an expression in which the declared values may be used. One possible translation of this could be as a block in Java. Inside a block in Java, a number of variables may be defined. This corresponds to values declared in a **let** expression. The block should end with the translation of the value expression in the **let** expression. When the execution leaves a block in Java, the variables defined within the block are no longer accessible, which correspond to the fact that names defined in RSL for the values in the **let** declarations can only be used between the keywords **in** and **end**.

7.3.6 Case Expressions

Even though Chapter 2 provides a translation for the **case** expression in RSL, the translation was not complete, because only some of the patterns where translated. The idea of the translation described earlier is good enough, namely that a **case** expression corresponds to a number of if statements in Java, and that the patterns should be translated as conditions of the if statements.

The product pattern could be translated like the record pattern by checking the type using an **instanceof** expression and to define local variables for each part of the product which may be used in the translation of the value expression in the case branch in RSL.

The list pattern comes in two forms. The first form is an enumerated pattern, where each value expression in the list is compared with each value expression in the pattern. The second form the pattern is a concatenated expression. The first form of the list expression could be translated as an infix expression in Java using the `&&` operator. Each element of the list is compared with translation of the corresponding element in the pattern. An example of the translation of an enumerated list pattern is shown in Example 7.2. The translation of the second form of a list pattern is not as simple as the enumerated list pattern. The concatenated list expression contains two patterns which must both match: an enumerated list pattern and an inner pattern, which may be a number of different patterns. The maximal type of the two pattern parts must be equivalent, i.e. they must both be a list of the same type. The first criterion of a match is that each element in the enumerated list pattern must match the first part of the value expression being matched. The second criterion is depending on the type of the second pattern. A wild card has the effect that only the first criterion must match. If the second pattern is a list pattern, then the rest of the list must match

Example 7.2 Idea of translation of list pattern in a case expression.

case l **of**
  ⟨4,5,6⟩ → ...
end

```
if(l.get(1).equals(4) &&
   l.get(2).equals(5) &&
   l.get(3).equals(6)
) {
...
}
```

the list pattern. In case the second pattern is an identifier, then only the first criteria must match, the rest of the list must be declared as a variable, which can be used in the translation of the value expression of the case branch.

An equality pattern should add a criterion to the condition of the if statement. An equality pattern stating that a part of a record pattern or an element of a list must be equal to some value. The translation of an equality pattern should be as shown in Example 7.3.

Example 7.3 Idea of translation of an equality pattern in a case expression.

case hd(cl) **of**
  empty → ...
  add(=White, tail) → ...
  add(=Black, tail) → ...
end

```
if(cl instanceof Empty) {
...
}
else if(cl instanceof Add and cl._v1() instanceof Black) {
...
}
else if(cl instanceof Add and cl._v1() instanceof White) {
...
}
```

7.3.7 For Expressions

A **for** expression in RSL runs through a finite list and evaluates an expression for each member of the list. The syntax is as follows:

for binding **in** value_expr$_1$ **do** value_expr$_2$ **end**

Where the binding may be used in the evaluation of value_expr$_2$.
This looping construct corresponds very much to the new syntax allowed for for–loops in Java 1.5:

```
for(FormalParameter : Expression) Statement
```

Expression must evaluate to an object implementing the interface *java.lang.Iterable*.
FormalParameter corresponds to the binding.
Expression should be the translation of value_expr$_1$.
Statement should be the translation of value_expr$_2$.
An example of the translation is shown in Example 7.4.

Example 7.4 Translation of a for–loop.

```
variable
   result : Real
value
   fraction_sum Int → write result Unit
   fraction_sum(n) ≡
      result := 0.0;
      for i in <1..n> do
         result := result + 1.0/(real i)
      end
```

```
public double result;
public fraction_sum(n) {
    result = 0;
    for(i : (new RSLListDefault(1,n)).getList()) {
        result = result + 1.0/((double) i);
    }
}
```

7.3.8 While Expressions

A while expression in RSL evaluates some value expression repeatedly as long as some other value expresion is evaluated to **true** at the start of each

iteration. This corresponds very much to the idea of a while statement in Java. The syntax of the RSL expression is shown below along with the translation in Java.

while value_expr$_1$ **do** value_expr$_2$ **end**

Where value_expr$_1$ must be of type **Bool**.
Translation in Java:

```
while (ve1) {ve2}
```

ve1 is the translation of value_expr$_1$ as an expression in Java.
ve2 is the translation of value_expr$_2$ as a statement in Java.

7.3.9 Until Expressions

An **until** expression in RSL evaluates some value expression repeatedly until some other value expression is evaluated to **true** at the end of an iteration. The value expression which is to be evaluated repeatedly in an **until** expression in RSL is a least evaluated once, because the test of the conditional value expression is evaluated at the end of the iterations. In Java, there is a do–while construct, which is also evaluated at least once. The difference between the two is that a do–while construct is continued as long as some expression evaluates to true in the end of each iteration, whereas the **until** expression runs until the condition is met. However, the same effect can be obtained in Java by negating the conditional expression. The idea is shown below:

do value_expr$_1$ **until** value_expr$_2$ **end**

Where value_expr$_1$ must be of type **Bool**.
Translation in Java:

```
do {ve1} while(!ve2)
```

ve1 is the translation value_expr$_1$ as a statement in Java.
ve2 is the translation of value_expr$_2$ as expression in Java.

7.4 Translating Larger Subsets of RSL

One of the most valuable extensions of this project would be to extend the translator to translate a larger subset of RSL. This extension would lead to better possibilities for specifying other tools in RSL. It is possible to extend

one part of the translator without extending the rest. The three modules which take care of the translation process may be changed individually. However, if the front end is extended without extending the translation module, some kind of error handling should be added.

My suggestions for the best approach to extend the translator developed in this project are to:

1. Extend the specification of *RSLAst_Module* to a representation of the full RSL.
2. Extend the visitors traversing the RSL Ast to the full RSL.
3. Extend the front end to parse the full RSL.
4. Extend the specification of *JavaAst_Module* to a representation of the full Java language.
5. Extend the visitors traversing the Java Ast to the full Java language.
6. Extend the translation module in a number of steps.

The reason for first extending the specification of the *RSLAst_Module* and the *JavaAst_Module* to the full languages, is that the work then can focus entirely on adding translation of more constructs. The front end and back end would not have to be changed for each of the steps of extension of the translation module. If the full languages are supported in the front end and the back end then they only have to be changed if the languages change.

Ideas for extensions of the translation module were treated in Section 7.3.

Chapter 8

Conclusion

This final chapter summarizes and evaluates the main results of this work.

8.1 Results

The objectives of this project were:

1. To define a *translation* from a subset of RSL into Java, and,
2. to develop a tool, called a *translater*, for translating from RSL into Java according to the defined translation.

These objectives have been fulfilled as discussed in the following. In Section 1.2, some requirements for the translation and the associated translator were stated, each of these requirements and the fulfillment of them will be discussed in the following.
The following was required of the translation:

1. The translation into Java must be semantically equivalent to the specification in RSL.
2. In the Java translated from a specification it should be possible to recognize the specification.

The first requirement of the translation has been fulfilled in the sense that there has been given a discussion of the sensebility of each of the translations defined. The semantics of the two languages have not been defined in formal way that makes it possible to prove the correctness of the translation. Therefore only an informal discussion of the sensibility of the translations has been given. The discussion of the sensibility of the translation was given in Chapter 2.

The recognizability requirement of the translation has been fulfilled in the sense that each translation into Java tries to use constructs in Java which are similar to the constructs in RSL.
The following was required of the translator:

1. The translator should translate a subset of RSL into Java according to the translation defined.

2. The translator should provide extensibility.

The requirement of the translator to translate a subset of RSL into Java according to the translation defined has been fulfilled in the sense that the implementation of the translator is based on the translations defined. The translator has been tested, as described in Chapter 6. The translator is able to translate a number of examples as well as the specification of the translation module. The requirement of the translator to be open for extension is fulfilled in the sense that the design of the translator is modular making it possible to change each of the modules individually. Furthermore, the translation module has been developed using a bootstrapping process opening for a larger subset of RSL to be translated by specifying the new translations in RSL. These possibilities for extending the translator have been shown in Chapter 7.

8.2 Concluding Remarks

This project has been a learning experience for me. The project has given me a better understanding of both the languages. Furthermore, the project has given me a better understanding of the design of a language processor as well as the development of a translator.

The work in this project has shown that it is possible to define a reasonable translation from a subset of the specification language RSL into the programming language Java. Furthermore, the work in this project has shown that even though the subset translated in this project is small, it is strong enough to specify a translation module and thereby also other tools for manipulating languages. The report gives suggestions both for how to extend the subset translated and for how to extend the tool developed.

It is my hope that this project can inspire the development of other tools for RSL and thereby increase the interest for applying formal methods in the development of software.

Appendix A

Using the Translator and Extending the Translator

A.1 Using the Translator

A.1.1 Tools Needed

To use the translator, a number of tools have to be present at the machine.

- Java 1.5.0 or a later edition. More precisely at least J2SE 5.0 or later.
- I have renamed the following commands: java to java1.5 and javac to javac1.5 to be able to have both a J2SE 1.4.* SDK and a J2SE 5.0 in the path.
- An editor for RSL (A this point *emacs* is the obivous choice since the existing tools only work with emacs).
- The type checker for RSL, rsltc. It is not strictly necessary but very handy for controlling that the syntax of RSL is correct before trying to translate it.

A.1.2 Setting up the Translator

Before the translator is ready to be used, a few things needs to be set up. The executable version of the translator has been compiled with J2SE 5.0. If another version of Java is installed on the local computer the source code must be recompiled using the steps listed in Section A.2 without modifying the specifications and source code.

- Copy the executable code of the translator from the provided cd to a directory on the local computer. The executable code for the second version of the translator can be found in the following path: `executable_version_50SE/second_version`.
- Add the directory containing translator to the class path of the system. To avoid having to use the classpath parameter whenever the translator is used.

You should now be ready to try out the first example.

- Copy the specification `LISTSUM.rsl` and `default.properties` from the provided cd to a directory on the local computer. The examples can be found in the directory `examples`.
- Execute the translator on the specification, by the following command in the directory: `java1.5 translator.Runner2 LISTSUM`.
- Compile the translated Java source code: `javac1.5 LISTSUM.java`.
- Execute the compile Java source code: `java1.5 LISTSUM`.

A.1.3 Controlling the Translation Process

The translation is controlled by a property file. The default name of this file is `default.properties` in the current library but another file may be specified as the second argument to the translator. The properties which may be controlled are listed below:

Property Functionality

extensiondir Directory where to look for files which are extended.

writeExtensionFiles Whether or not to write the files generated from translation of base class expression in an extending class expression.

writeFiles Write the result of the translation.

writeFilesDir Directory where the result is written.

createVisitorMethods Whether or not to create visitor methods for the types translated.

visitor The name of the visitor class used in the implementation of the visitor design pattern.

package Inserts a *package* declaration in the top of the classes generated.

import Libraries to import seperated by $.

getMethods Function names which should be translated as dynamic methods, seperated by $.

ignoreList Base classes in RSL not translated, seperated by $.

printRSL Whether or not to print the specification to stdout.

printJava Whether or not to print the translated Java to stdout.

extraMethodFile ASCII file containing extra methods which must be added to the main class in translation.

A.2 Extending the Translator

The directories referenced in this section are relative to the root of the cd provided or the directory to which the content of the cd is copied.

A.2.1 Tools Needed

To extend the translator, the tool mentioned in section A.1.1 must be present as well as the following:

- An editor for Java and ANTLR.
- ANTLR

A.2.2 Extend the Front End

To extend the front end the following steps must be taken:

1. Copy the directories `specification` and `source/second_version` to the local computer.
2. Add constructs to the specification: RSLAst_Module2. Found in directory `specification/second_version`.
3. Translate the module using the `rslast2.properties` as property file. `rslast2.properties` can be found in directory: `specification/second_version`. If the directory: `source/second_version/translator/rslast2` not already exists it must be created.

4. Add RSL constructs which must be recognized to the `rsl2rslast.g` grammar file which can be found in: `source/second_version/translator/syntacticanalyzer`.
5. Generate the new `RSLLexer` and `RSLParser` by using ANTLR: `java1.5 antlr.Tool rsl2rslast.g` in directory: `source/second_version/translator/syntacticanalyzer`.
6. Add visit methods to a least `TM_RSLAstVisitor` and the following visitors if needed:
   (a) `TM_StringRSLAstVisitor.java` to be able to print the RSL.
   (b) `TM_ParentRSLAstVisitor.java` to be able to find the parent construct in the type decoration phase.
   (c) `TM_TypeDecorateRSLAstVisitor.java` if the construct added must be type decorated in some way.

   The visitors can be found in the directory: `source/second_version/translator/lib`.
7. Compile the Java files in the following directories: `source/second_version/translator/lib`, `source/second_version/translator/rslast2`, and `source/second_version/translator/syntacticanalyzer`.

A.2.3 Extend the Translation Module

To extend the translation module, the following steps must be taken:

1. Copy the file `Translator_Module2.rsl` and `translator2.properties` to the `specification/second_version` directory on the local computer (If not already done in extension of the front end).
2. Add or changes functions in the specification Translator_Module2. Translator_Module2 can be found in the directory: `specification/second_version`.
3. Translate the module using the `translator2.properties` as property file, it can be found in directory `specification/second_version`. If the directory `source/second_version/translator` not already exists it must be created.
4. Compile the Java files in the following directory: `source/second_version/translator`.

A.2.4 Extend the Back End

To extend the back end, the following steps must be taken:

1. Copy the files `specification/second_version/JavaAst_Module.rsl`, `specification/second_version/javaast2.properties`, and the directory `source/second_version/translator/lib`. (If not already done in the previous steps).

2. Add constructs to the specification: JavaAst_Module2. JavaAst_Module2 can be found in the directory: `specification/second_version`.

3. Translate the module using the `javaast2.properties` as property file, it can be found in directory `specification/second_version`. If the directory `source/second_version/translator/javaast2` not already exists it must be created.

4. Add visit methods for to both `TM_JavaVisitor` and `TM_StringJavaVisitor` which can be found in `source/second_version/translator/lib`.

5. Compile the Java files in the following directories: `source/second_version/translator/lib` and `source/second_version/translator/javaast2`.

Appendix B

Content of CD

The content of the CD is listed below. Directories are written as `directory`. Content:

`source`

- `first_version` contains source code for the first version of the translator.
- `second_version` contains source code for the second version of the translator.

`executable_version_50SE`

- `first_version` contains precompiled code for the first version of the translator, compiled for J2SE 5.0.
- `second_version` contains precompiled code for the second version of the translator, compiled for J2SE 5.0.

`examples` contains a number of examples and a `default.properties` file.

- `version_2_only` contains an example which only works with the second version of the translator.

`specification`

- `second_version` contains the specification files and property files for the different modules.

Appendix C

Formal Specification

C.1 First Specification, Intermediate Version

C.1.1 Translator_Module

context: RSLAst_WrapperModule_2

```
scheme Translator_Module =
  extend RSLAst_WrapperModule_2 with
